EE 589/689 Foundations of computer vision: Lecture notes Fall quarter 2006, OGI/OHSU

Miguel Á. Carreira-Perpiñán

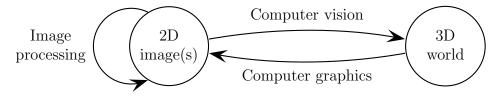

Based mainly on: David Forsyth and Jean Ponce: Computer Vision. A Modern Approach. Prentice-Hall, 2003.

Introduction to computer vision

Computer vision has been around since the 1960s. Recent developments:

- Increasing availability of cheap, powerful cameras (e.g. digital cameras, webcams) and other sensors.
- Increasing availability of massive amounts of image and multimedia content on the web (e.g. face databases, streaming video or image-based communication).
- Increasing availability of cheap, powerful computers (processor speed and memory capacity).
- Introduction of techniques from machine learning and statistics (complex, data-driven models and algorithms).

Three related areas:

- Computer graphics: representation of a 3D scene in 2D image(s).
- Computer vision: recovery of information about the 3D world from 2D image(s); the inverse problem of computer graphics.
- Image processing: operate one one image to produce another image (e.g. denoising, deblurring, enhancement, deconvolution—in particular in medical imaging).

Some problems of computer vision:

- Structure-from-motion (3D reconstruction from multiple views, stereo reconstruction)
- Shape-from-X (single image):
 - shape-from-texture
 - shape-from-shading
 - shape-from-focus
- Segmentation
- Tracking
- Object recognition

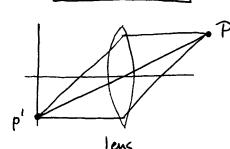

A few applications of computer vision:

- Structure-from-motion:
 - Throw away motion, keep structure: image-based rendering (e.g. 3D models of buildings, etc. for architecture or entertainment industry)
 - Throw away structure, keep motion: mobile robot control (we know the structure but not the robot location)
- Image collections:
 - Image retrieval: find me pictures containing cars and trees
 - Image annotation: textual description of objects in image
- Finding faces in a group picture, crowd, etc.
- Recovering articulated pose of a person from a video
- Medical applications:
 - Image enhancement
 - Segmentation of brain
 - Image registration or alignment: compare brains of different people, or brains before/after lesion
 - Blood vessels: track cells
 - Unobstrusive patient monitoring
- HCI: track eye motion; recognize physical gestures (e.g. sign language)

CH. 1: CAMERAS

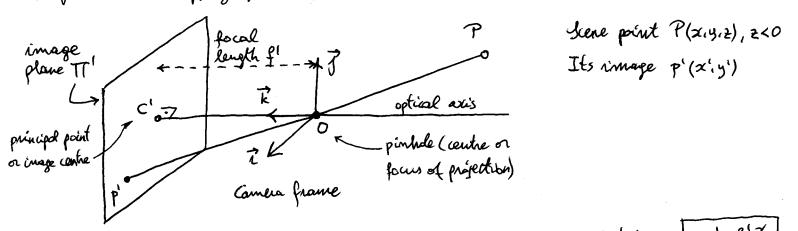

We don't have direct access to the physical world, but indirect access through the camera(s). How does the connera map the world to the image?

1.1. PINHOLE CAMERA: consider comera-centred coordinate system, assume pinhole = point (ignores blurring due to finite size, diffraction due to small size). [FIG. 1.2, 1.3]

Leuses are ruch to gather more light (in pinhole cameros, each single point p' receives a single ray so quite dock) and focus it (= force all rays coming from world point P to converge on the same image point). Leuses also introduce aberrations (spherical, chromatic...)

Projection = mapping from scene point to image point:

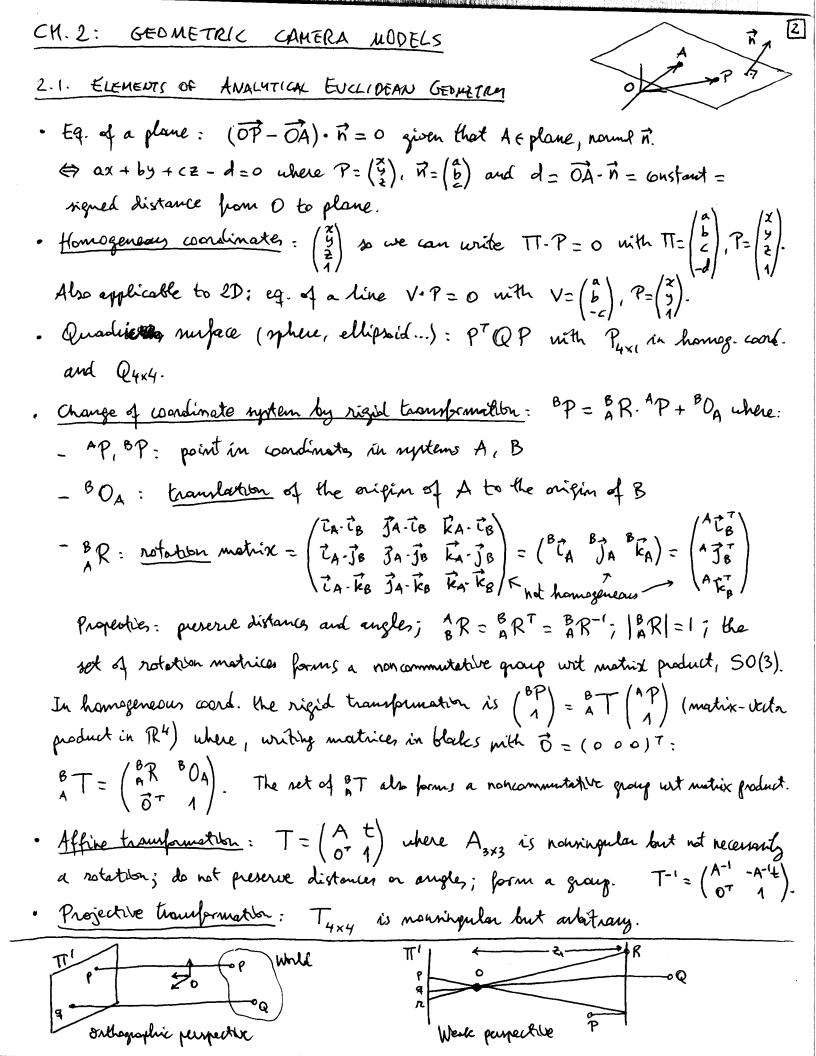

* <u>Perspective projection</u>: P, O, p' collinear $\Rightarrow \overrightarrow{OP}' = \lambda . \overrightarrow{OP} \Rightarrow \begin{cases} x' = \lambda x \\ y' = \lambda y \Rightarrow \\ z' = \lambda z \end{cases}$ nonlinear; does not preserve distances or angles, but does map lines into lines. $y' = f' \frac{y}{z}$

* Affine projection: useful approximation to perpective proj.

- Weak purpective: scene depth << distance to camera $\Rightarrow Z \propto Z_r$ contant $\Rightarrow y' = -my$ where $m = -\frac{f'}{Z_r} > 0$ is the magnification; linear.
- Orthographic projection: comera always at a constant distance from scene; normalise m = -1 for simplicity $\Rightarrow \begin{bmatrix} \chi' = \chi \\ \chi' = \chi \end{bmatrix}$ (usually unrealistic). $\chi' = \chi$ bee fig. in next page $\Box = \Xi$

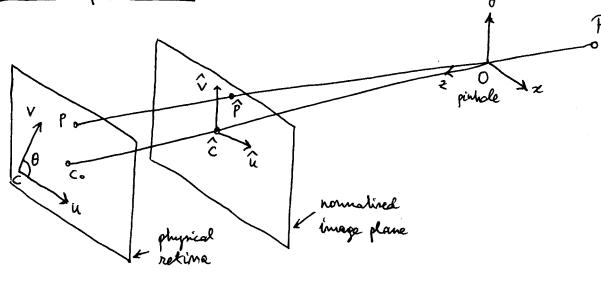

[1

2.2. CAMERA PARAMETERS & THE PERSPECTIVE PROJECTION Consider an external, arbitrary world world word. Eys. different from the camera world. Eys. The world and camera coord. mys. are related by a set of physical parameters: - Intrinsic : relate the commens's physical coordinate system to the idealised coord. sys (focal length of lens, nice of pixels, portion of principal point, shew). - Extrinic: relate the comera's cord mys. to a fixed world coord. syst. and specify

its position and orientation in mace.

- · Normalined image plane: pavallel to image plane at distance 1 from pichole. Perspective projection ($\hat{u} = x/z$
- . <u>Physical retina</u> (pixel coord.) at distance f = 1 from pinhole with image coord. expressed as rectampular pixel units "le pixel, magnification &= kf, B= lf and displace. ment $\binom{u_0}{v_0}$ of the retina's origin: $\begin{cases} k = \alpha x/2 + u_0 \\ V = \beta y/2 + v_0 \end{cases}$

 $u = x \frac{x}{z} - x \cot \theta \frac{y}{z} + u_0$ The retina coordinate nymen may be sliphtly showed by an angle $\Theta : \left\{ V = \frac{\beta}{2}, \frac{y}{2} \right\}$ • Change of coordinates (in homogeneous coord.): $p = \begin{pmatrix} y \\ y \end{pmatrix}, \hat{p} = \begin{pmatrix} y \\ y \end{pmatrix}, P = \begin{pmatrix} y \\ y \end{pmatrix}$ +10

-Normalised -> retina: p= Kp with matrix of intrinsic parameters K= (0 B vo) - Conner \rightarrow retina : $p = \frac{1}{2}MP$ where $M = (K O)_{3\times 4} = \frac{1}{3\times 3} = \frac{1}{3} = \frac{1}{3$ - Conners -> mormalized: $\hat{p} = \frac{1}{2} \begin{pmatrix} I & O \\ 3x3 & 3x1 \end{pmatrix} P$

The infinite parameters are generally known from the manufacturer (pixel nite, skew) but not always (eg. stock film factage, zoom). Particular cases: 2010-skew $(0=\frac{T}{2})$, unit aspect rafts $(\alpha = \beta)$.

* Extrinsic parameters: now camera frame
$$\neq$$
 world frame, related by nigid transformation:
perspective projection eq. world \Rightarrow retina $p = \frac{1}{2}MP$ with perspective projection multiplication $M = K \cdot (R \ t) = \begin{pmatrix} x \pi_1^7 - x \cot \Theta \ \pi_2^7 + u_0 \pi_3^7 \\ \frac{\beta}{100} \ \pi_2^7 + v_0 \pi_3^7 \\ \frac{\beta}{100} \ \pi_3^7 \\$

2.3. AFFINE CAMERAS AND AFFINE PROJECTION EQUATIONS

Weak purplective (scene's relief
$$\ll$$
 distance to comerce): $\begin{pmatrix} x \\ y \\ z \end{pmatrix} \rightarrow \begin{pmatrix} x \\ y \\ z_h \end{pmatrix}$
• Comera \rightarrow normalized: $\begin{pmatrix} \hat{u} \\ \hat{v} \end{pmatrix} = \begin{pmatrix} x/z_h \\ y/z_h \end{pmatrix} = \frac{1}{Z_r} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 2n \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix}$ in metrix notation.

• Would \rightarrow netrina: P = MP with $M = \frac{1}{Z_2} K \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 & 2n \end{pmatrix} \begin{pmatrix} R \\ 0 & 1 \end{pmatrix}$ with $\begin{cases} \text{calibration matrix } K \\ \text{extraining parameters are caughed, we can write <math>\binom{u}{v} = MP$ with $\begin{cases} \text{calibration matrix } K \\ \text{extraining parameters are caughed, we can write <math>\binom{u}{v} = MP$ with $\begin{pmatrix} M \\ 2x4 \end{pmatrix} = \frac{1}{Z_2} \begin{pmatrix} k & s \\ 0 & 1 \end{pmatrix} \begin{pmatrix} R_2 & t_2 \end{pmatrix}$ where R_2 , $t_2 = \text{first two nows of } R, t$, and k and s are the 2x3 + 2x1 aspect ratio and skew of the camera. Thus the weak -perspective projection matrix is defined by 2 intriving parameters (k, s), 5 extraining parameters $(3 \text{ angles in } R_2, 2 \text{ coord.}$ in t_2) and 1 scene-dependent parameter Z_n . Dethographic projection : fix $Z_T = \text{constent}$ (eg. $Z_n = 1$). For one camera only.

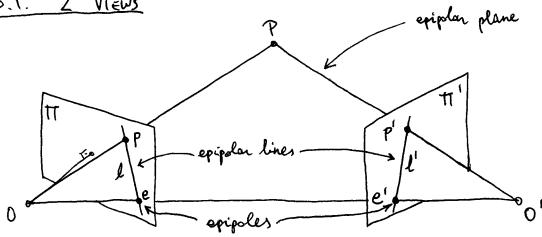

CH. 3: GEOMETRIC CAMERA CALIBRATION

- The problem of estimating the intrinsic (extrinsic personneters of a camera.

Set up a calibration rig (pattern): set of points on lines with known positions wit would frame [F16.3.1]
Calibration as an optimisation problem: minimise (e.g. by least-squeres) the discrepancy between the observed carnera features and their positions predicted by the perspective eqs. We know for i=1,..., N the carnera image p: of nord point Pi ⇒ { pi = ½ MPi } is an overcourtrained (N > # params) system of nordinear eqs, so minimise ∑ ||Pi - ½ MPi ||² by gradicit descent, Newton....
Photogrammetry: engineering field whose aim is to recover quantitative geometric information from ≥ 1 pictures. Applications: cartography, military intelligence, city planning, etc.

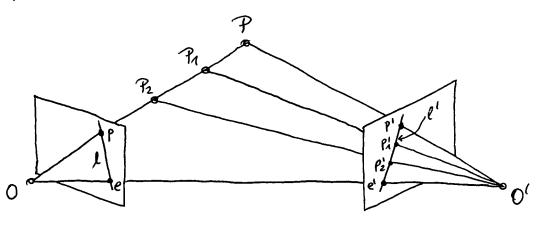

CH. 10: THE GEONETRY OF MULTIPLE VIEWS 5 Depth is not directly accemble in a single image, but it can be meanned through triangulation from > 2 images: - Most animals have > 2 eyes on move their head to detect depth - An autonomous robot is equipped with a stereo or motion analysis system. Objective: understand the geometric & algebraic constraints that hold among multiple views of the same scene: - 2 views: epipolar constraint, represented by 3×3 essential/fundamental motive - 3 views: 3×3×3 trifocal sensor

- etc.
- 10.1. 2 VIEWS

- consider the normalized camera haves TT, TT' (we could also draw then behind the pinholes but it is simpler in (rout).
- World point P deserved by 2 comeros (with aptical centres 0, 0' and retives TI, TI') as images p. p'.
- P, O, O', p, p' & epipolar plane defined by rays OP, OP.
- Epipale e' = projection of artical centre O on retina H' (ditto for e), ie, where one comera is seen by the other.
- Epipela line l'associated with p: intersection of epipelar plane and retina IT; contains p' and the epipele e'.

- Epipelan constraint: if p and p' are images of the same works point than p' must [6] lie on the epipelon like anociated with p. In other words, the world point and the two optical centres lie on the same plane, thus given a point in one image, its correspondent must lie on a known like in the other image.
- Application: <u>searching for corresponding points</u>. If we have a stereo rig with calibrated cameras (known infrience & extrinic parameters) then if we know the image p in one camera, we can determine the epipolar line l'where the other image p' must lie and limit our search there.

<u>Calibrated case</u>: intrimic parameters known, so p = p̂. Epipelar contraint means: \overrightarrow{Op} , \overrightarrow{Op}' , $\overrightarrow{OO'}$ coplanar \Leftrightarrow $\overrightarrow{Op} \cdot (\overrightarrow{OO'} \times \overrightarrow{O'p'}) = 0$ formos. \overrightarrow{Oord} . p · (t × (Rp!)) \Leftrightarrow $\overrightarrow{P^{T} E p' = 0}$ with the <u>essential multice</u> E = [t_x]R: \overrightarrow{Op} $\overrightarrow{Oo'}$ Rotatou $\pi' \rightarrow \pi$ - E is defined in terms of normalized coordinates (and independent of p, p'). - [a_x] = Neew-symmetric matrix such that $[a_x]x = a \times x$; $[a_x] = \begin{pmatrix} 0 & -a_3 & a_2 \\ a_2 & 0 & -a_1 \end{pmatrix}$. - E has 5 degrees of freedom (3 from R, 2 from t because scale invariant). - Ep' = epipelar line anociated with p' in the first image $E^T p = \frac{\pi}{2}$ $\frac{\pi}{2}$ $\frac{\pi}{2}$ $\frac{\pi}{2}$ p $\frac{\pi}{2}$ second $\frac{\pi}{2}$ (by symmetry). - E^Te = -R^T[t_x]e = 0 because t || e ⇒ E is singular; in fact, rank(E)=2 and its 2 singular values are equal. - Only one epipelar line goes through any image point, except for the epipele. All epipelar lines of one camera go through the other's epipele. - Ex: pue translation ("eyes"): t = (t_a o)^T, R = I ⇒ V = V' (horizontal line).

Small motions: moving camera with translational velocity
$$\vec{V}$$
 and retational velocity \vec{w} .
Call $\vec{p} = \begin{pmatrix} \vec{w} \\ \vec{v} \end{pmatrix}$ the velocity of point p (motion field). Then, rewriting to first order
 $p^{T} \equiv p' = 0$ for two frames separated by an sufficient model time interval St :
 $\vec{E} = St \cdot \vec{V}$
 $R = I + St \cdot [w_{X}]$ replecting
 $p' = p + St \cdot \vec{p}$
 T us translation; $w = 0 \Rightarrow (p \times \vec{p}) \cdot V = 0$
 $p = p + St \cdot \vec{p}$
 $p = p + St - \vec{p}$
 $p = p + St -$

★ Uncalibrated case: intrinsic parameter unknown, so
$$p = K\hat{p}$$
, $p' = K'\hat{p}'$ (3×3
calibration matrices K, K' , normalized image coord. \hat{p}, \hat{p}') $\Rightarrow \hat{p}^T E \hat{p}' = 0 \Rightarrow$
 $p^T F p' = 0$ with the fundamental matrix $F = K^{-T}EK^{-1}$:
- F to defined in terms of pixel coordinates
- F has 7 d.o.f. (defined up to scale); (10.6): parametrisologn in terms of epiples' coord.
- Fp' = epiplar line anomated with point p' in the first image (ditto F^Tp for p in 2^m
- rouck (F) = 2, Fe' = 0, F^T E = 0.

* Weak calibration

- The problem of estimating F from a set of n correspondences between 2 images taken by conneces with unknown intrinsic parameters.
- In principle, 8 points in general position are enough to determine the T elements of F (nince the solution is defined up to scale we can set $F_{33} = 1$): solve linear system on F: pi F p' = 0, t=1,...,8 (eight-point algorithm by Longuet-Higgins), see eq. after (10.7). To avoid numerical instabilities, the coord. 4 the corresponding points should be normalised so that the entries of the eqs. pi F p' = 0 are comparable in size.

FIG. OF STERED PAIR

8 CORRESPONDENCES

- It to more roburt to use n>8 correspondences: min \$\sum{\sum{2}}{2}\$ (\$p\$, \$F\$, \$p\$)^2\$, quodustic in F.
 Both methods ignore the rank-2 property of F. Possible approach: make zero the smallert singular value of F.
 \$P\$ F\$p\$' is proportional to the algebraic distance from \$p\$ to the epipelar line \$F\$p\$' (or from \$p\$' to \$F\$'p\$), so can also minimize the mean squared geometric distance
 - between the image points and the corresponding gripplan lines: $\sum_{i=1}^{\infty} (d^2(p_i, Fp_i) + d^2(p_i, F^*p_i))$ - We can also determine F by fint calibrating each camera, but this requires estimating 11 parameters per camera.

CH. 11: STEREOPSIS

- Derign & implementation of algorithms that minuic our ability to latest depth from the image recorded by our two eyes.
- Applications in relatingation, cartography, aerial reconnaisance, computer graphics (contruction of 3D scene models), etc. [FIG. 11.2]
- Ateres vision involves two processes:
 - Furing features observed by ≥ 2 eyes (hard)
 Reconstructing their 30 preimage (easy)
- Assume calibrated cameras (intrinsic & extrinsic parameters known wit fixed wold frame). <u>11.1. RECONSTRUCTION:</u> given a calibrated steres rig and 2 metching points p.p': reconstruct the sene point P.

* 20 care : disparity = difference in retribut position
$$d = p' - p$$
.
We detain the depth z by triangulation, ie, by
intersecting the rays Op and O'p'. The triangles
 $p'Pp'$ and $\overrightarrow{OPO'}$ are nimilar so:
 $\frac{t+p-p'}{z-f} = \frac{t}{z} \Rightarrow z = f\frac{t}{d} \Rightarrow$
The depth is inversely proportional to the disparity
(distant objects seem to more slowly than close ones).

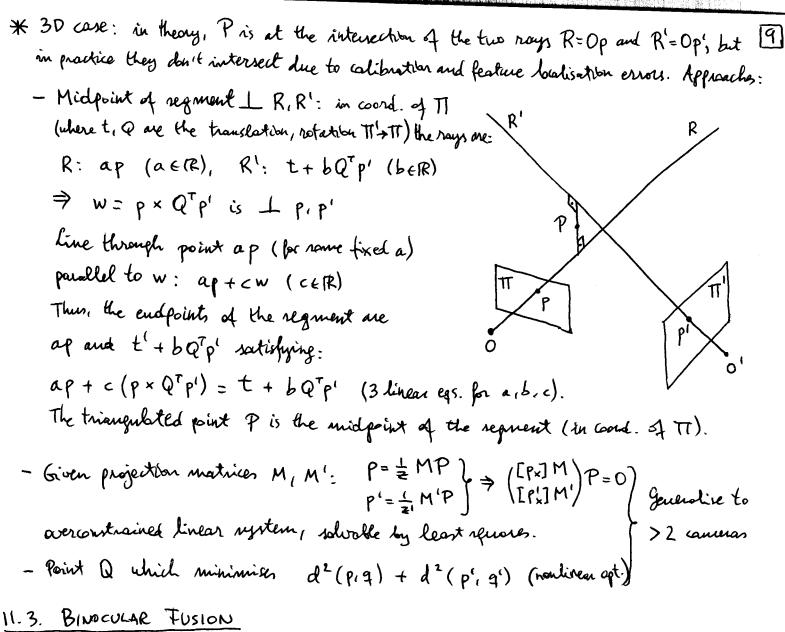

FIG. 11.2

- Hand to know what point pairs correspond in both images because there are many pixels and many features (eg. edges) in every image.
- We arrive that most scene points are visible from both concernes and that corresponding image regions lask minilar.
- Approach: <u>correlation</u>: compare the intensity people in the neighbourhood of potential matches by using the correlation: correl $(u, v) = \left(\frac{u-\overline{u}}{\|u-\overline{u}\|}\right) \cdot \left(\frac{V-\overline{v}}{\|v-\overline{v}\|}\right) \in [-1, 1] = cosine of angle between$ normalised vectors.It can be computed efficiently by recursion (ex. 11.7).

internity profile on windows of fixed rite

11.4. USING MORE CAMERAS further redules the ambiguites, eg. a 3rd image can be used to check hypothetical matches from the first 2 images. [F(G. 11.16]

CH. 12: AFFINE STRUCTURE FROM MOTION

- The mobiles of estimating the 3D shape of a scene from multiple pictures.
- Particular care: sterlopsis (intriunic param. known, extrinnic param. letermined wrt fixed world coord. mys.), simpler.
- Converses' positions and possibly intrinsic param. unknown and may change over time.
- Applications;
 - . Image-based rendering: video recorded using hand-held camera (possibly zoaming) is used to capture the shape of an object and then render it under new viewing conditions.
 - · Active vision systems : capable of hynamically madifying the camera parameters (intrinnic (extrinnic), eg. mobile robot mavigation.
- We assume the projections of n points have been matched across m pictures (correspondence problem) and focus on the purely geometric structure-form-motion problem:
 - · estimate 3D positions of corresponding serve points (seene structure) . estimate projection matrices of the cameras (motion of the points with cameras)
- Assumption: scene's relief << depth so the perspective projection is approximated by the affine projection.

Given n fixed points P; (j=1,...,n) observed by maffine commences we have their imape, (nonhomogeneous coord.) $p_{ij} = M_i \begin{pmatrix} P_j \\ 1 \end{pmatrix} \xrightarrow{M_i = (P_i \cdot b_i)}_{2 \times 4} A_i P_j + b_i , j = 1, ..., n.$ Structure-fron-motion problem: estimate {Mi}i= and {Pj}i= from {Pij}ij=1. We have 2 m n egs. and 8 m + 3 n unknowns (sufficiently constrained for large enough m, n). - Affine ambignity: Mi, Pj are solutions => MiQ, Q-1 (Pj) are solutions, where Q = (C) is an arbitrary affire transformation matrix (C3x3 nousingular, D3x1). Thus, the solutions are only defined up to an affine transformation. If the intrinsic param. are known (Ki = I and use normalized image word. pij) then Mi must svery additional constraints which can eliminate the ambiguity. This neggests: 1. Find a 3D reconstruction up to an affine transformation using > 2 views (essential put). 2. Use additional views and courtraints from known calibration to find a unique 3D reconstruction (Euclidean upgræde). The ambiguity still occurs for perspective purjection (projective ambiguity).

[10]

12.2. AFFINE STRUCTURE AND MATING FORT Two LANGES [4]
Mighbaic motion estimation:
$$P = AP + b \\ P' = A'P + b' \} \Leftrightarrow \begin{pmatrix} A & P - b \\ A' & P' b' \end{pmatrix} = 0. A particular distance is the point of t$$

12.3. AFFINE STRUCTURE AND MOTION FROM MULTIPLE IMAGES

* Tomari-Kanade factorisation approach: given m images of n pints $P_1, ..., P_n$, define the $2m \times n$ data matrix $D = (q_1 ... q_n) = AP$ with $q_i = \begin{pmatrix} P_1 \\ P_n \end{pmatrix}$ for point P_i , $P = (P_1 ... P_n)$ is $3 \times n$, and $A = \begin{pmatrix} A_n \\ P_n \end{pmatrix}$ is $2m \times 3$. Thus rank(D) = 3, though in practice D has full rank due to image raise, errors in bradisation of image points, and the fact that converse are not really affine. If $D = UWV^T$ is the SVD of D, with $U_{2m \times n}$ orthogonal, $W_{n \times n}$ diagonal with singular values with ≥ 0 , and $V_{n \times n}$ orthogonal, then $D_3 = U_3 W_3 V_3^T$ (converpto the largeA 3 singular values) is the best rank-3 approximation to D in the Frabanics norm sense, it; it minimizes:

$$\sum_{i,j} \|P_{ij} - A_{i}P_{j}\|^{2} = \sum_{j} \|q_{j} - AP_{j}\|^{2} = \|D - AP\|_{F}^{2} \text{ over } A_{2m\times 3}, P_{3\times n}.$$

Thus, we can take $A = U_3$ and $P = W_3 V_3^T$ as representative of the (affine) camera motion and scene shape, respectively. Note again the affine ambiguity: $D = (AQ)(Q^{-1}P)$ is also a solution,

War Eren AFTE TO TUGLOGRA / Marker: reliable, simple.

Disadvantages: uses affine comera model (an externion exists for perspective projection, but it doesn't always converge to the correct solution); all points must be visible in all image. * It is also possible to use a 2-view algorithm image by image, carefully selecting correspondences 12.4. From AFFINE TO EUCLIDEAN [MAGES]

* Euclidean constraints & calibrated affine cameron:

Weak perpective: M = (A b) = 1/(k s)(R2 t2) where R2, t2 cantain rows 1-2 of rotation, translotion, translotion, calibrated ⇒ use normalised image cord (k=1, s=0) ⇒ M = 1/2n (R2 t2) ⇒ A2x3 has orthogonal rows.
Outographic purpective: Zn=1 ⇒ A2x3 has orthonormal rows. (cannot recover depth 2).
When contraints: all cameras have the same intrinsic priameters.
K comprising Euclidean upopades from multiple vews: Euclidean upprade = effice transformation Q4x4 = (CD) that maps the affire shape arts the Euclidean thape: M=(AC AD+b), P=C⁻¹(P-D).
Assume m ≥ 3 images and convider the ortographic case for signification. Then the Euclidean cantaints in the pollowing overconstrained system of 3 m eqs:

12

$$\hat{a}_{i1} \hat{a}_{i2} = 0$$

$$\hat{a}_{i1} CC^{T} a_{i2} = 0$$

$$= - q_{i1} a_{i1} CC^{T} a_{i2} = 0$$

$$= - q_{i1} a_{i2} CC^{T} a_{i2} = 0$$

$$= - q_{i2} CC^{T} a_{i3} = 0$$

$$= - q_{i2} CC^{T} a_{i4} = 0$$

$$= - q_{i2} CC^{T} a_{i4} =$$

We can only recover Q up to rotations of C (nine CC^T is invariant to them) [F16. 12.7] and translations D, ie, up to rigid motions of the world (\$ given the images we cannot know the longitude/latitude, or what is N-S-E-W; for that we need absolute coord. I some wold points. 12.5. AFFINE MOTION SEGMENTATION

- By reducing the data matrix to its row-echelon form and applying connected-components we obtain one group of points corresponding to each object; but not robust with noise.
- Shape interaction matrix (Costeina-Kanade): assume we know the assignments of points to dejects and write for each object i= 1,..., k:

Data matrix
$$D^{(i)} = \begin{pmatrix} p_{n1}^{(i)} \cdots p_{1n_i}^{(i)} \\ \vdots \\ p_{mn}^{(i)} \cdots p_{mn_i}^{(i)} \end{pmatrix}, \quad M^{(i)} = \begin{pmatrix} M_n^{(i)} \\ \vdots \\ M_m^{(i)} \end{pmatrix}, \quad P^{(i)} = \begin{pmatrix} p_{n1}^{(i)} \cdots p_{n_i}^{(i)} \\ 1 \cdots 1 \end{pmatrix} \Rightarrow$$

$$D = (D^{(1)} - D^{(k)}), M = (M^{(1)} - M^{(k)}), P = diag(P^{(1)}, - P^{(k)}), h = \sum_{i=1}^{n} h_{i_i},$$

$$z_{m,k'k} = \frac{1}{4kkn} + \frac{1}{4kkn}$$

D = MP, thus rank $(D) \leq 4k$. Each object traces a different 40 mbospace when undergoing rigid motion (4 dof per object, or less for planes (3) or lines (2)).

- Compute the SVD of D for its 4k largert n.v. D = U4k W4k V4k (= in the noiseless case, ~ in the noisy case). The 4k-dim subspace spanned by the souss of D is the same as that spanned by the rows of either P (unknown in punctive) or V4k (known).
- Thus the nxn matrix Z = Vyk Vyk (shape interaction matrix):
- · is uniquely defined (pf. Z = Z V:V:")
- . maps R" onto the 4k-dim subspace spanned by the rows of Vik
- is block diagonal because P is block diagonal, thus the cluster structure is more doubles in 2 them in D (pf. define M = UW¹/₄ Q, P = Q⁻¹W¹/₄ V^T₄ up to affine tranel. ⇒ VV^T/₄ = P^T(PP^T)⁻¹P.) In practice the points from each object are not ordered within D or 2, so Z is not block diagonel over all nows h columns permutations; blocks (clusters) are then detected in the permuted matrix Z. Once we know which point belongs to which doject, we can recare each doject independently. [F1G. 12.8]

CH. 14: SEGMENTATION CLUSTERING BY

- Segmentation (= grouping, perceptual organisation) is the mid-level vision problem of:
 - · Obtaining a compact representation of helpful information in the image (generally speaking)
 - . More specifically, breaking the imoge into regions of coherent colour & texture; often a first step for object recognition.

[14]

It is not well befined, though in MMARIA applications (eg. cytology) it is possible to define and evoluate à more specifically.

- Churtening : general peddem of splitting a data set into meaningful groups (clusters). Not well defined either and not clear how to evolute the quality of a clustering result, but bots of algorithms in statistics and machine learning which are useful in practice.
- Jegnuntation as dustning: Junter pixels (or other image features edge, likes, etc.) into meaningful sequents, using a clustering algorithm.
 - Ch. 15: segmentation as fitting (fit a model much or a line or Gaussian mixture). 1-1-1-
- Examples:
 - . Unter apeyscale à colour image vito segments.
 - . Aunter a set of edges into lines (edge = (location, orientation)).
- What cuteria should a segmentation method use to decide ubich pixels/features belog to gether?
- 14.2. HUMAN VISION: GROUPING & GESTALT
- Context affects how things are perceived
- Gertalt school of psychology: grouping = tendency of the visual system to perceive certain things in a picture together.
 - · EX: sequents of different length are priceived differently in different waterts. [FIG. 14.2]
 - . this often separate the image into figure (the significant object) and ground (the background on which the figure lies).
 - . Factors which predispose a set of element to be granted: [PAG. 306-307]
 - . Also happens in the perception of speech & sound.
 - · Ecological argument: things are grouped together because doing so produces representations that are helpful for the visual world:
 - * common fate: the components of objects tend to mare together
 - * symmetry: many real dijects are roughly symmetric * continuity is useful to explain occlusion 5- occluding object
 - F16. 14.6 * continuity is useful to explain occlusion FIG. 14.8 1 - rellusory contour

5

FIES. 14.9, 14.10

ghat boundary detection;

- Long reprences of video convist of reveral shots (editing) = much shorter subsequences that show largely the same object (eg. TV news: auchor vs event footage).
- Want to detect the shot boundaries & represent each shot by a key frame (meful to summarise the content of a video for quick browsing).
- Alg. 14.2: that boundary datection using interframe differences Boundary occurs whenever dist (Fn+1, Fn) > O. - Jonne definitions of distance:
 - . Frame differencing : must the square, of the differences at each pixel. Semptive to comera shakes.
 - . Histograme distance: between claur histograms of each frame. Insensitive to spatial anngement of colours in the frame (thus to small shaking).
 - · Black comparison: yelt frame in blacks, compare histograms in each black and take the largest black difference.
 - · Edge differencing: instead of comparing pixel values, compare edges.

14.4 Image Segmentation by CLUSTERING PIXELS

* mag features: - Pixel intensity on colour; bout use RGB, use a uniform colour space suchas LUV on LAB where Euclidean distances between feature vectors motich perceptual distances between clours (rel 6.3.2). - Pixel position (i, j) in the image (nearby pixels are likely in the same object). - Histogram of colours on grey levels (for distance between clusters) - Texture: compute the histogram over a reasonably sized window of the outputs of a allection of filters spanning a range of scale and orientation. The distance in the feature space may be represented with a weighted cucliferer distance. * Merarchical Instainz methods : they naturally yield a hierarchy of dusters: partition the data set toto groups that we dissimilar, recursively - Divisive (top-down): partition groups. - Agglomerstive (bottom-up): merge date points llot are nimilar into groups, recursively merge groups. Both are greedy aporthous: at each step they find the best split or merge. - What is a good intercluster listance? · Single-link dustering: distance between donest elements; tends to yield extended dusters. · Complete-link : distance between farthert element; tends to yield rounded cluster. . Average-link " : average distance between all elements -, also rounded cluster. - How many clusters are there ? 4 5 listance Difficult to tell; may examine the dendergrown generated by the algorithm. (hard: too many pixels) on use some 5 6 threshold on the distance or number of clusters. applementive single-link durtering * K-means

⇒ minimise \$ over CA,..., CK E IR⁰ (so need to assume there are k clusters).

Can't test all cluster combinations (lunge number) so iterative algorithm.

- Algorithm: choose k data points as cluster centres; iterate till there is no change in druter centres: · allocate each date point to its closest cluster centre (needs care to avoid empty chesters) · update durter centres as the means of each durter [prove it] Each step decreases \$ on leaves it unchanged; \$ is bounded below. Thus the algorithm converges - but to one of the many local optime of of (not recentarily the global one). FIGS. 14.13 - 14.15

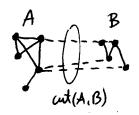

14.5. SEGMENTATION BY GRAPH-THEORETIC CLUSTERING

- -Idea:
 - · Build a graph where vertices = data points, edges' weights = given by a similarity (affinity) function which is large of the the vertices are similar and small otherwise. > needs { graph · but the graph into good molecopher (= chuters) = many strong edges within molecopher, few
 - (which we cut) between subgraphs. => needs objective function for graph cut.
 - FIG. 14.16 • Affinity meanines : unally Gaussian $e^{-\frac{1}{2}\left(\frac{d(x,y)}{\sigma}\right)^2}$ where the distance d(x,y) is modulated loy a scale parameter. [F16-14.18]

* Spectral dustering

- I dea: the hustering structure in the date is etchanced in the eigenvector of the affinity matrix A. In an ideal case, and = 0 for points if in different clusters, thus A is block-diagonal (if we rearder the data by clusters). Then, the eigenvectors of A are eigenvectors of the blacks padded out with zeroes (and act as cluster indicators. Ex: for k=2 clusters: $A = \begin{pmatrix} A_n & o \\ o & A_2 \end{pmatrix} i \quad if u_n is eigenvector of A_n \neq A_n u_n = \lambda_n u_n \Rightarrow A \begin{pmatrix} u_n \\ o \end{pmatrix} = \lambda_n \begin{pmatrix} u_n \\ o \end{pmatrix}$ elements < 2010, not ellester 1 nonzero, cluster 1 In partice, A is not exactly block-disponal; all the elements of each eigenvector are nonzero. Thresholding them FlG. 14.19 - 14.20 can still recover the dusters in some cases.
- * Normalised cuts

- I dea: wit the proph into 2 connected components such that the cost of the cut is small wot the uncut edges in each compohent: min <u>cut (A, B)</u> + <u>cut (A, B)</u> where: - cut (A, B) = sum of weights of edges crossing between A and B. · assoc(A,V) = u u u " V (V= all vertices).

F165. 14.23-14.24

Mean-shift clustering

Represent each pixel \mathbf{x}_n , n = 1, ..., N by a feature vector as in spectral clustering, typically position & intensity (i, j, I) or colour (i, j, L^*, u^*, v^*) .

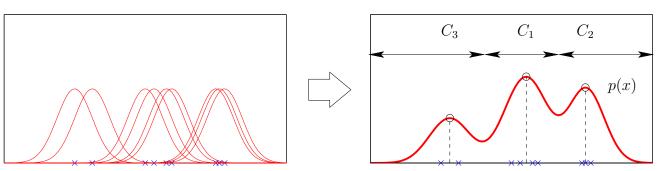

Idea: define a function that represents the density of the data set $\{\mathbf{x}_n\}_{n=1}^N \subset \mathbb{R}^D$, then declare each maximum as a cluster representative and assign each pixel to a maximum via the mean-shift algorithm.

Kernel density estimate (smooth multivariate histogram) with bandwidth σ :

$$p(\mathbf{x}) = \sum_{n=1}^{N} p(n) p(\mathbf{x}|n) = \frac{1}{N} \sum_{n=1}^{N} K\left(\frac{\mathbf{x} - \mathbf{x}_n}{\sigma}\right) \qquad \mathbf{x} \in \mathbb{R}^{D}$$

The kernel K satisfies $\int K(\mathbf{x}) d\mathbf{x} = 1$ and $K(\mathbf{x}) \ge 0$ (so the kernel is a pdf). Typical kernels:

- Gaussian (infinite support): $K\left(\frac{\mathbf{x}-\mathbf{x}_n}{\sigma}\right) \propto \exp\left(-\frac{1}{2}\left\|\frac{\mathbf{x}-\mathbf{x}_n}{\sigma}\right\|^2\right)$
- Epanechnikov (finite support): $K\left(\frac{\mathbf{x}-\mathbf{x}_n}{\sigma}\right) \propto \begin{cases} 0, & \left\|\frac{\mathbf{x}-\mathbf{x}_n}{\sigma}\right\| > 0\\ 1-\left\|\frac{\mathbf{x}-\mathbf{x}_n}{\sigma}\right\|^2, & \text{otherwise} \end{cases}$

Mean-shift algorithm for Gaussian kde: maxima (also minima, saddle points) of $p(\mathbf{x})$ satisfy

$$\mathbf{0} = \nabla p(\mathbf{x}) \propto -\frac{1}{N} \sum_{n=1}^{N} e^{-\frac{1}{2} \left\| \frac{\mathbf{x} - \mathbf{x}_n}{\sigma} \right\|^2} \left(\frac{\mathbf{x} - \mathbf{x}_n}{\sigma^2} \right) \propto p(\mathbf{x}) \sum_{n=1}^{N} p(n|\mathbf{x}) (\mathbf{x} - \mathbf{x}_n) \Longrightarrow \mathbf{x} = \sum_{n=1}^{N} p(n|\mathbf{x}) \mathbf{x}_n = \mathbf{f}(\mathbf{x})$$

with "shifts" $\mathbf{x} - \mathbf{x}_n$ (thus $\nabla p(\mathbf{x}) \propto \text{mean shift}$) and posterior probabilities (by Bayes' th.)

$$p(n|\mathbf{x}) = \frac{p(\mathbf{x}|n)p(n)}{p(\mathbf{x})} = \frac{\exp\left(-\frac{1}{2} \|(\mathbf{x} - \mathbf{x}_n)/\sigma\|^2\right)}{\sum_{n'=1}^{N} \exp\left(-\frac{1}{2} \|(\mathbf{x} - \mathbf{x}_{n'})/\sigma\|^2\right)}.$$

This shows that the fixed points of \mathbf{f} are stationary points of p, and suggests defining a fixed-point iterative scheme by starting from a data point \mathbf{x}_n and iteratively applying \mathbf{f} till convergence (and repeating this for all pixels). It is possible to prove that this algorithm converges from nearly any initial \mathbf{x} to a maximum with linear convergence rate (in fact it is an EM algorithm).

Advantages:

- Nonparametric clustering: only need to set σ .
- No step size needed.

- Works well with clusters having complex shapes.
- The number of clusters is determined automatically by σ .

Disadvantages:

- The mean-shift iteration is slow.
- Large total computational cost: $\mathcal{O}(kN^2)$ where k = average number of mean-shift iterations per pixel ($k \approx 20\text{--}100$). Accelerations are possible that produce almost the same segmentation.

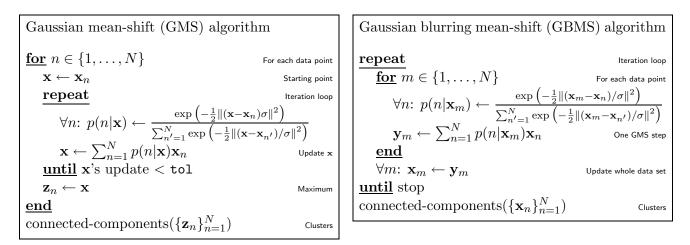

Figure 1: Pseudocode. The "connected-components" step collects all equivalent but numerically slightly different points.

Mean-shift blurring clustering

Like mean-shift clustering, but actually move data points at each step. It obtains very similar segmentations to those of mean-shift clustering but quite faster (cubic convergence rate for Gaussian clusters): the total computational cost is still $\mathcal{O}(kN^2)$ but k is quite smaller ($k \approx 5$). It is related to spectral clustering, since effectively the algorithm is iterating ($\mathbf{X} \leftarrow \mathbf{P}\mathbf{X}$, update \mathbf{P}) where $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_N)$ and $\mathbf{P} = \mathbf{D}^{-1}\mathbf{A}$ (stochastic, random-walk matrix), and $A_{mn} = \exp\left(-\frac{1}{2} \|(\mathbf{x}_m - \mathbf{x}_n)/\sigma\|^2\right)$ are the Gaussian affinities and $\mathbf{D} = \operatorname{diag}\left(\sum_{n=1}^N A_{mn}\right)$ the degree matrix.

Exercises

- 1. Derive the mean-shift algorithm for a general kernel K.
- 2. Prove that the mean-shift algorithm is gradient ascent on $p(\mathbf{x})$ with an adaptive step size.
- 3. Derive the mean-shift algorithm for the Gaussian kde with a bandwidth that is a full covariance matrix Σ_n for each point.

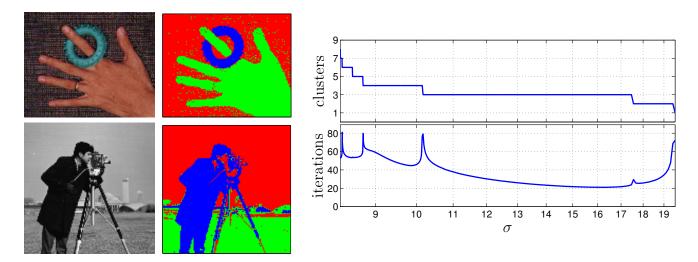

Figure 2: Segmentation results with GMS for hand 50×40 .

CN. 15: SEGMENTATION BY PITTING & MODEL

- Impertant because images often contain straight links: buildings, machines... - It all the points that belong to a particular line y = ax+b are known: - Least-aquares: minimise errors in y (verticel distance): any min $\lesssim ||y_i - (ax_i+b)||^2 \Rightarrow (\frac{x_i}{x}, \frac{x_i}{y}) \binom{a}{b} = (\frac{y_i}{y})$ - Total least-squares: minimise point-line (orthogond) distances: symmetric wat x, y; better fit than LSQ.

22

Whithing the line as ax + by + c = 0 with $a^2 + b^2 = 1$, the distance $\binom{x}{2}$ -to-line is lax+by+cl [prove it] ⇒ any min ≥ (axi+by:+c)² nt. a²+b²=1 ⇒ {Lagrange mult. $\begin{pmatrix} \overline{x}^{i} & \overline{x}y & \overline{x} \\ \overline{x}y & \overline{y}z & \overline{y} \\ \overline{z} & \overline{y}z \end{pmatrix} \begin{pmatrix} a \\ b \\ c \end{pmatrix} = \lambda \begin{pmatrix} a \\ c \\ c \end{pmatrix}$. From the last row we get $c = -(a\overline{x}+b\overline{5})$ [= centre of mass $\in live$] and mostituting it back we get $\Sigma - {a \choose b} = \lambda p {a \choose b}$, an eigenvalue problem whose solution is the largest eigenvector (principal component). In general, the k principal components give the best total LSQ fit using a k-dim subspace. - Which point is on which like? Combinatorial rearch space. <u>k-means for lines</u>: armene k lines and minimise $\sum_{k=1}^{\infty} \sum_{k=1}^{\infty} k_{k}$ dist $(l_{i_1}z_{j_1})^2$ over correspondences and likes by iterating: · allocate each point to its closest like · update lines by fitting to their points Instialise with random lines, or random arrighments; stop when the likes change little, or when no labels have changed, or when the objective protion changes little. 15.3 FITTING CURVES Same dijective (minimise sum of squared point-to-auve distances) but more difficult, so une approximations. Anune différentiable curves. * Implicit curves: condinates naticly an eq. $\phi(x,y) = 0$ (= zero level of nucleue ϕ), typically a polynomial eq. = algebraic unves: degree 2 are the conic sections (like, circle, ellipse, hyperbola, paraloda; [TAB. 15.1]), higher-oder polynomille rarely (x,y) Sixtence from point (x,y) to encore $\phi(x,y)=0 =$ distance from (x,y)to closent point as (y,y) in the used because it is diffiult to get a stable fit. (orthogonal to the arrive and the arrive normal at (u,v) is $(\frac{\partial \phi}{\partial x}, \frac{\partial \phi}{\partial y})|_{(u,v)} \Rightarrow$ $(u, v) \text{ verifies } \begin{cases} (u, v) \in arrive: \\ \text{tongent at } (u, v) \perp (\overline{z}, y)(u, v) : \\ (\overline{z}, y)(u, v) : (\overline{z}, y)(u, v) : (\overline{z}, y)(u, v) : (\overline{z}, y)(u, v) = 0 \end{cases} 2 eqs. \text{for}$ Jolvalke in principle, but many solutions (including maxima, saddles). Ex. ellipse 450-In genard, for a polynomial of order d, we have two eqs. (each a poly of 250order d) with up to d2 solutions. Thus it is practically better to use approximations such as the algebraic distance $\phi(x,y)$, which is 0 iff $(x,y) \in anne, zeneralises to higher$ dimension & (eg. implicit surfaces) and yields an earier numerical problem.

Since $\mu \phi(z_1,y) = 0$ represents the same curve $(\mu \neq 0)$, the algebraic dictance should be normalised; $\frac{\phi(z_1,y)}{\|\nabla \phi(z_1,y)\|}$ is useful, and exact for straight lines. Both approximations behave as expected for points near the surve (since, by Taylor's th., $\|\phi\|$ increases as we go away from the curve) but farther away they may not.

15.4 FITTING AS A PROBABILISTIC INFERENCE PROBLEM

- 15.5 ROBUSTNESS
- (Total) least squares places a large weight on large errors and is thus sensitive to outlies (often caused by measurement errors on correspondence errors), which can reverely briss the estimated line. [FIG. 15.7]

Approaches:
- modify the model to use heavy tails for the noise (M-estimators).
- twinduce an explicit onthier model (M. 16. 2. 4).
- search for points (hat seem to be good (RANSAC).

$$\frac{M}{2} = estimators$$

Optimisation problem: $E(\Theta) = \sum_{k=1}^{N} P(\frac{n_i(x_i;\Theta)}{residual}; \sigma)$

nobsamples (to see if we hit on one with few outlies). Also, update scale during doutions [25] (ree rule in bode). [F16. 15.9-15.10]

Idea: search the data set for good points (= not outliers), i.e. points producing madely that match many of the remaining points. For example, to fit likes: - choose sample (n points drawn umfarmly at random)] + random) repeat k times and choose the best fit of them - fit line to it

- Number of samples n = minimum number of prints needed to fit (2 for a like, 3 for a circle ...). - Number of iterations le : if w ∈ (0,1) is one estimate of the fraction of good points in the dataset, then the probability that an n-sample is good is (approximately, assuming scompling with replacement) p= w". Thus the number of draws Kneeded to get one good sample is distributed as a geometric distributed of parameter p: $P[K=k] = (1-p)^{k-1}p \text{ which has} \begin{cases} \text{mean } E[K] = \frac{1}{p} \left[lf. \text{ we } E[k] = \sum_{k=1}^{\infty} k P(k) = -p \frac{2}{p} \sum_{k=1}^{\infty} (1-p)^k \text{ and} \\ \frac{2}{p} \sum_{k=1}^{k} \frac{2}{(1-p)} \sum_{k=1}^{\infty} \frac{2}{(1-p)^k} \sum_{k=1}^{\infty} \frac{2}{(1-$ Then take k = mean + a few standard deviations to be on the safe ride. Or, take k such that $(1-p)^k$ is small enough.

to for fundamental matrices.

CH. 16: SEGMENTATION AND FITTING USING PROBABILISTIC METHODS

- Ch. 15: methods using local models of rimilarity (= comparing pairs of pixels), now probabilistic. - Ch. 16: global schedels based on probability (hat explain a large dataset {Xi};=1 in terms of a prival number of parameters.
- 16.1 MISSING DATA PROBLEMS, FITTING AND SEGMENTATION
- Assume there is an underlying complete data set consisting of {(xi, mi)}, where xi is the feature vector and mi the source or component it comes from:
- Sequenting about images into regions: sources of about (perhaps stricts) that quenote the pixels. - Sequentity tokens toto colliberar groups: sources = likes - Sequentize a motions requesse into maring regions: sources of motion (dijects) that get. the pixels. If we doserved the source of each si (eg. if we know which point belorged to which like), this would be a fitting public (ears).
- * <u>Ex. 16.1: unage segmentation</u>. probabilistic mixture model for a pixel feature $x \in \mathbb{R}^{2}$ assuming M components, with parameters Θ :
 - $p(x; \Theta) = \prod_{m \geq i}^{M} P_m(x|m) p(m) = \prod_{m \geq i}^{M} P_m(x; \Theta_m) T_m \text{ where}$ $P(m) = T_{im} \in (0, 1), \text{ with } \sum_{m \geq i}^{M} T_m = (: \text{ probability a priori of component } m (mixing weight))$ $P(x|m) = p_m(x; \Theta_m): \text{ probability model for } x \text{ from component } m, \text{ with parameter } \Theta_m;$ $e_{i} \cdot P_m(x; \Theta_m) = |2TT \Xi_m|^{-\frac{1}{2}} e^{-\frac{1}{2}(x-\mu_m)^2 \Xi_m^{-1}(x-\mu_m)} (\text{coursion with mean } \mu_m, \text{ courses } \Theta_m).$ Both p(x) and $P_m(x; \Theta_m)$ for each m are probability humbles functions (pdf). $[T_{i}, \dots, T_{m}] \text{ ris a probability mass function <math>(pnmf).$ Total parameters for $p(x; \Theta): \Theta = \{(T_a, \Theta_a), \dots, (T_{i}\pi, \Theta_m)\} = \{(T_{im}, \mu_m, \Xi_m)\}_{m=1}^{M}.$ $P(x|FiGURE) p(x) = P(x; \Theta): \Theta = \{(T_a, \Theta_a), \dots, (T_{i}\pi, \Theta_m)\} = \{(T_{im}, \mu_m, \Xi_m)\}_{m=1}^{M}.$ $P(x|FiGURE) = P(x; \Theta): \Theta = \{(T_{i}, \Theta_{i}), \dots, (T_{i}\pi, \Theta_m)\} = \{(T_{im}, \mu_m, \Xi_m)\}_{m=1}^{M}.$ $P(x|FiGURE) = P(x; \Theta): \Theta = \{(T_{i}, \Theta_{i}), \dots, (T_{i}\pi, \Theta_m)\} = \{(T_{im}, \mu_m, \Xi_m)\}_{m=1}^{M}.$ $P(x|FiGURE) = P(x; \Theta): \Theta = \{(T_{i}, \Theta_{i}), \dots, (T_{i}\pi, \Theta_{i})\} = \{(T_{im}, \mu_m, \Xi_m)\}_{m=1}^{M}.$ $P(x|FiGURE) = P(x; \Theta): \Theta = \{(T_{i}, \Theta_{i}), \dots, (T_{i}\pi, \Theta_{i})\} = P(x; \Theta)$ $P(x|FiGURE) = P(x; \Theta): \Theta = \{(T_{i}, \Theta_{i}), \dots, (T_{i}\pi, \Theta_{i})\} = P(x; \Theta)$

For segmentation, we have $\{x_i\}_{i=1}^N$ but not $\{m_i\}_{i=1}^N$ and nont to: 1. Determine $\{\Theta m\}_{m=1}^M$ and $\{TT_m\}_{m=1}^M$ (to fit the model). 2. Determine m_i from $p_m(m|x_i)$ using Bayes' the (to request the image). 26

Objective function: maximum likelihood fit $p(x_i; \Theta)$ or equivalently maximum $\log_{|x|}$ itselftood $L(\Theta) = \sum_{i=1}^{\infty} \log p(x_i; \Theta)$ (unally simpler): - Assumes points $\{x_i\}_{i=1}^{\infty}$ drawn itsel (independently identically listributed); unrealistic because neighbouring pixels are not independent, but simplifies the estimation. - Many nonlinear optimisation methods may be used but a particularly mainster are for mixture models is the EM algorithm. - If we know $\{m_i\}_{i=1}^{\infty}$ we could fit $p_m(z; \Theta_m)$ to its features $\{x_i\}$ vay earily (fitting a caussia). [Q: animing the true presenters Θ that among to a given image, be sampling N pixels from $p(z; \Theta)$

- produce a realistic image?] $\underbrace{\mathsf{K}} \underbrace{\mathsf{Ex. }}_{(6.2: \ \text{fitting line, to point sets:}} assume M line, in the plane. each with parameters$ $<math>\mathcal{O}_{\mathsf{M}}$ (slope, intercept) and take as pdf for \mathbf{i} a token w a mixture $p(w) = \underbrace{\Sigma}_{\mathsf{M}} \prod_{n \in \mathbb{N}} p_n(w|\mathcal{O}_n)$ with total parameters $\Theta = \{\mathsf{H}_{\mathsf{M}}, \mathcal{O}_{\mathsf{M}}\}_{n=1}^{\mathsf{M}}$. Given observed tokens $\{w_i\}_{i=1}^{\mathsf{N}}$, meximise the likelihood $\prod_{d \in \mathbb{N}} p(w_i|\Theta)$ over Θ . Again, if we knew which token was from what line, we could fit each live separately.
 - Mixture modelling and the EM algorithm

pererally, in mixture modelling the component histophiston p(x(m)) are simple distribution with parameters Θ_m (eg. Gaussian with mean pm, covariance Ξ_m), while the mixture $p(x) = \sum_{m=1}^{M} \operatorname{Trm} p(x|m)$ (with parameters $\Theta = (\operatorname{Trm}, \Theta_m)$) is a more complex but note powerful model. Fifting a single component separately is generally easy, eg for a Saussian the maximum likelihood estimate is the sample mean and covariance [prove it] - it doesn't reque an iterative optimisation algorithm. Maximising the log-likelihood can be done by noticean aptimisation (eg. gradient descent, Neutris method...) but the optimisation algorithm is often complicated (eg. A needs to respect contraints: $\operatorname{Trm} \in (o, i)$, $\Xi \operatorname{Trm} = (, \operatorname{covariance modules$ are positive definite...). However, for mixture models (and more perevelly for missing detaproblems) there exists a general frequencies to kerive an iterative optimisation algorithm,the <u>EM (expectation-maximisation)</u> algorithm, which usually is very simple to implement(though putness complicated to derive for a first problem), converge globally (from any initialproblems) and respects the constraints (uncelly).

I dea: given an initial estimate of the parameters
$$\Theta$$
:
 Ξ step: estimate the (distribution of the) missing data)
 M step: fit by maximum likelihood the parameters Θ enuming the missing data estimate)
 EM is a "soft" version of k-nucleus where the correspondence, between components $m=1,...,M$
and data points $\pi_1,...,\pi_N$ are not brinary but continuous-valued: $p(m|\chi_{\xi}) \in (o, 1)$.
Thus, in the M step each component m fits its parameters to all the later but each data
point contribute proportionally to its weight $p(m(\chi_k))$.
 EM for mixture models: assume a complete-dataset $\{(\pi_i, m_i)\}_{i=1}^N$ where $m_i \in \{1,...,M\}$
is the index of the component where π_i came from j we only observe $\{\pi_i; \pi_{i=1}^N, and want to artimize the mixture parameters $\Theta = \{T_{i}, 0, 0, 0, 1\}$.$

to estimate the mixture parameters
$$\Theta = \{ \pi_{m}, \Theta_{m} \}_{m=1}$$
 by maximizing the log-likelihood
 $L(\Theta) = \sum_{i=1}^{N} \log p(x_{i} | \Theta) = \sum_{i=1}^{N} \log \sum_{m=1}^{M} \pi_{m} p(x_{i} | M_{i} | \Theta_{m}),$

$$E step : assuming the current value for The parameters $(O^{old}, compute the distribution of the missing data $p(mi|x_i; \Theta^{dd}):$

$$p(mi|x_i; \Theta^{dd}) \xrightarrow{\text{Bayes'th.}} \frac{p(x_i|m_i; \Theta^{dd}) p(m_i; \Theta^{dd})}{p(x_i; \Theta^{dd})} = \frac{p(x_i|m_i; \Theta^{dd}) \tau_{mi}}{\sum_{i=1}^{M} p(x_i|m_i; \Theta^{dd}) \tau_{mi}} = W_{im_i} \in (0, 1)$$$$$

and write the expected complete-data log-likelihood : constant function of
$$\Theta$$

 $Q(\Theta; \Theta^{dd}) = \sum_{i=1}^{N} E_{p(m_i|x_i;\Theta^{dd})} \{\log p(x_i, m_i; \Theta)\} = \sum_{i=1}^{N} \sum_{m_i=1}^{M} W_{im_i} \cdot \log p(x_i, m_i; \Theta)$

M step: maximise the expected complete-data log-likelihood over the parameters:
$$\Theta^{new} = arg max Q(\Theta; \Theta^{dd})$$

It can be shown that the likelihood $L(\Theta)$ increases or bosy through after each EM iteration and that (under certain conditions) the algorithm converges to a bool maximum likelihood estimate Θ^* . [Pf: use Jensen's inequality: $\log(\sum_{i}a_ib_i) > \sum_{i}a_i\log b_i$ if $a_i, b_i > 0$. to show that $Q(\Theta; \Theta^{dd}) - Q(\Theta^{dd}; \Theta^{dd}) < L(\Theta) - L(\Theta^{dd})$.) \Rightarrow the increase in log-likelihood is at least as much as the increase in Q, but Q is easier to aptimize: no $\log \sum_{m=1}^{\infty} 1$.] 16.2 THE EM ALGORITHM IN PRACTICE

$$\begin{split} & \text{16.2.1 Example: image eigenstation with Gaussian mithues: ensure N data point, $z_{i_{1}\cdots,z_{N}}$
(or fartue settor per pixel) and model z or a facultur mithues: when N data point, $z_{i_{1}\cdots,z_{N}}$
(or fartue settor per pixel) and model z or a facultur mithue with M comparents:
• composed m as a Gaussian with parameters p_{m} , σ_{m}^{2} : $p(z_{1}^{m}) = (2\pi \sigma_{m}^{2})^{-\frac{p}{2}} e^{-\frac{1}{2} \left\| \frac{z_{1}-z_{1}}{\sigma_{m}} \right\|^{2}}$
• Gournian mithue is $p(z; \Theta) = \sum_{m=1}^{N} \operatorname{Trm} p(z_{1}^{m}) \mu_{m}, \sigma_{m}^{2}$.
E step: $\operatorname{Trm}, \mu_{m}, \sigma_{m}^{*}$ are the dd parameter value:
 $\operatorname{Winn} = \frac{P(z_{1}^{*}|m_{1}; f_{m}; \sigma_{m}^{*}) \pi_{m}}{\sum_{m=1}^{N} p(z_{1}^{*}|m_{1}; f_{m}; \sigma_{m}^{*})} = \frac{\operatorname{Trm}(2\pi \sigma_{m}^{2})^{\frac{p}{2}} e^{-\frac{1}{2} \left\| \frac{z_{1}-\mu_{m}}{\sigma_{m}} \right\|^{2}}{\sum_{m=1}^{N} p(z_{1}^{*}|m_{1}; f_{m}; \sigma_{m}^{*}) \pi_{m}} = \frac{\operatorname{Trm}(2\pi \sigma_{m}^{*})^{\frac{p}{2}} e^{-\frac{1}{2} \left\| \frac{z_{1}-\mu_{m}}{\sigma_{m}} \right\|^{2}}}{\sum_{m=1}^{N} p(z_{1}^{*}|m_{1}; f_{m}; \sigma_{m}^{*}) \pi_{m}} = \frac{\operatorname{Trm}(2\pi \sigma_{m}^{*})^{\frac{p}{2}} e^{-\frac{1}{2} \left\| \frac{z_{1}-\mu_{m}}{\sigma_{m}} \right\|^{2}}{\sum_{m=1}^{N} p(z_{1}^{*}|m_{1}; f_{m}; \sigma_{m}^{*}) \pi_{m}}} = \frac{\operatorname{Trm}(2\pi \sigma_{m}^{*})^{\frac{p}{2}} e^{-\frac{1}{2} \left\| \frac{z_{1}-\mu_{m}}{\sigma_{m}} \right\|^{2}}}{\sum_{m=1}^{N} \frac{P(z_{1}^{*}|m_{1}; f_{m}; \sigma_{m}^{*})}{\sum_{m=1}^{N} p(z_{1}^{*}|m_{1}; \Theta)} = \frac{1}{2} \operatorname{Trm}(2\pi \sigma_{m}^{*})^{\frac{p}{2}} e^{-\frac{1}{2} \left\| \frac{z_{1}-\mu_{m}}{\sigma_{m}} \right\|^{2}}}$
M ateq: mult $p(z_{1},m_{1}; \Theta) = p(m_{1}^{*}) \frac{p(z_{1}^{*}|m_{1}; \Theta)}{\sum_{m=1}^{N} \frac{p(z_{1}^{*}|m_{1}|^{2}}{\sum_{m=1}^{N} \frac{p(z_{1}^{*}|m_{1}|$$$

Once we have fitted the model (ie, we have parameter estimates TT_{m}^{*} , μ_{m}^{*} , σ_{m}^{*}), we can sequent by binanising the arrighment probabilities: pixel x_{i} goes to the sequent on that maximises $p(m(x_{i}; \Theta^{*}))$.

16.2.2 Example: line fitting: with component models probabilistically a line or follows: In descrived points (from that line) are generated by (1) choosing a point along the line and (2) puturboing it orthogonal to the line with Garessian noise: $\binom{\pi}{2} = \binom{\mu}{\nu} + n \cdot \binom{q}{b}$ where $\binom{\mu}{\nu}$ is a point on the line and bvtc=0, $a^2+b^2=1$ and $n \sim N(0, \sigma^2)$. Thus $p(x,y;a;b;c) \sim e^{-\frac{1}{2}\left(\frac{az+by+c}{\sigma}\right)^2}$ and we need a constraint $a^2+b^2=1$. If we have only one component then maximizing the loglikelihood $-\frac{1}{2\sigma^2}\sum_{i=1}^{\infty} (ax_i+by_i+c)^2 nt \cdot a^2+b^2=1$ becomes the total least equales estimate. [Problem: P(x;y;a;b;c) is an improper distribution because (p(x;y;a;c), dx, by diverges; but it still $defines a useful likelihood] <math>F(G \cdot (6.3-4)$

16.2.3. Example: motion requestation : motion represes often counist of large regions that have similar motion subjecting internelly. Assume the motion field comes from a mixture 16.2.3. Example: motion regimentation model (layered motion model). . It each wixed in the image there is a motion vector connecting it to a pixel in the next image (motion field). - Each mixture component is a parametric pdf for a motion fick. - The overall motion at each pixel is the mixture of M components. This model averages a set of M distinct, internally consistant motion fields alled layers which could come from a set of night objects at different depths and a moving camera. FIG. 16.5 given a represe with 2 image, we want to determine (a) which motion first a pixel below, to, and (b) the parameter values for each field. If is a missing data public where the missing data is the motion fick to which a pixel belongs. - Motion model: pixel $\vec{p}_1 = (u, v)$ in image 1 moves to $\vec{p}_2 = \vec{p}_1 + \vec{m} (\vec{p}_1; 0)$ in image 2. Common choice for motion model: affine motion $\overline{\mathcal{M}}(\vec{p}; \theta) = A\vec{p} + b$ with $\theta = \{A, b\}$. - So the intervity at these two pixels, I1(p1) and I2(p2), is the same up to measurement noise (ammed Gaussian with standard devisition $\overline{\sigma}$). - Expected - Complete - data log-tikelihood; $L(V, \Theta) = -\sum_{\vec{p},m} V_{\vec{p},m} \cdot \frac{1}{2} \left(\frac{I_1(\vec{p}) - I_2(\vec{p} + \vec{m}(\vec{p}; \Theta_m))}{\sigma} \right)^2$ Other advantages of layered motion models: they expose motion baudance; new requerces can be reconstructed. FIG. 16.6-7 16.2.4. Outlier model: define a mixture model where there is one component having beauzy tails which is dedicated to modelling outliers. I deally, this component catches the outliers and leaves the other components fiel to model the good points more accurately. (local aptima are still a problem). Missing data; whether a point is an arthier or not. Conssian p(x): biased mean, inflated variance Mixtue p(x) = Trpo(x) + (1-11)p1(x) outlier + made po - TT = frequency of arthices arthen good - po = arthier model, typically uniform are the range A \sim XX American of the Lata, F16.16.8 XX MAR LX X 16.2.5. Background motheration: missing data = whether a point is background or not. Could take both madels (blog, Theg) as Gaugsian (with different parameters). Ap(I|bkg) P(I|bkg) Fit parameters with EM using pixel intensities from an image requerce. Then classify each pixel I is a given image as background if not blog I p(bkg/I(x)) > p(bkg/I(x)). [F(G. 14.10-11 bkg

- * Advantages of the EM algorithm: arises naturally in missing data problems (in particular mixtures), [31] is remally simple to implement (eg no step sites) and increases the likelihood monotonically, uncolly converging from most initial points.
- * Difficulties with the Ett algorithm:
 - Like any other algorithm, EM converges to one local optimum of the likelihood function, of (possibly) many existing, which are uncolled anociated with the combinatorial nature of the search space. (eg the line fitting problem). The fillowing helps:
 - · Instituire EM from reveral different parameter values (possibly randomly chosen), then choose the best estimate (with highert likelihood value).
 - · Preprocess the data carefully, eg try to minimise noise and outliers; maybe use the Hough transform to greess good initial line fits.
 - . Use a better model, eg do not model the pisels independently.
 - Unlike other algorithms (eg. Newton's method, quari-Newton), EM has typically a linear convergence rate and is thus slow (slower the "more" data are missing), though accelerated versions exist. In some applications this may not mother if we are happy with a rough parameter estimate.

16.3 MODEL SELECTION: Which MODEL IS THE BEST FIT?

The missing data publicus we have discurred (and many then problems from prevous choptes) assume the number of components is known in advance. Finding the number of components is a <u>model relaction</u> publicus: each model has a different number of components (thus a sufferent number of generated) and we want to find the one that fits the data best. However, and we cannot use the value of the likelihead above, since (ynorig the issue of local optimus) this grows monotonically with the model site (more components \$ likelihead 1, error V). For example, we can fit to zero error any set of points by pointing a line through every pair of points. However, we prefer smaller models because : - Such a large model is unlikely to arrespond to reality and thus would generalize pools.

to a different date set measured from the some problem. By fitting extremely well the training set that we happen to have doserved, we may not fit well the date that we did not doserve (relection bias). (overfitting) - Smaller problems are computationally cheaper and more depart. [32] One approach to model relection is to minimize a weighted average of the negative log-likelihood (the data term) and a term that increases with the number of components (model relection term). There are several such terms which are useful in practice (P = # free parameters): N = # data points

- An information criterion (ALC): min L(@) + p
 - It ignores the number of data points and tends to averifit in practice, is to choose a model with the many parameters.
- Bayes information artendon (B(C): min L(D) + P/ log N.
- Description length (MDL): chose the model that encodes the data set most crisply in terms of transmission: encoding cost = (cost of encoding the model parameters) + (cost of encoding the late set given the model parameters). It yields BIC.

To minimize these active, one needs to tay different numbers of components M=1,2,3..., fitting the parameters @ for each M (possibly obtaining reveral estimates and choosing the best, to avoid bad local aptima), then evolution the outcion.

* <u>Cross-vehidation</u>: idea: mult the training set into two parts, then use one to fit the model (try different numbers of components) and the other to test the fit. A model with too many parameters will fit the first date set but not the second.

- . Uning a ningle choice of split still has relection tois; we could average over all such splits but this would be unwieldy.
- practically useful approximation: <u>leave-one-out cross-volidation</u>: fit a model to each (N-1)-paint model of the training set (there are N); compute the error on the remainsy points, and sum the errors to obtain an estimate of the model error. Choose the model that minimises that.

CH. 17: TRACKING WITH LINEAR DYNAMIC MODELS

Tracking in computer vision = inference about the motion of an object given a sequence of images. Applications:

- Motion capture: track a moving person, then render a cartoon cheracter on thousands of virtual extras in a crowd scene with realistic motion; or create slightly different motions (from the measured ones).
- Recognition from motion: identify an object on tell what it is big from its motion.
- Surveillance, targeting
- 17.1 TRACKING AS AN ABSTRACT PROBABILISTIC INFERENCE PROBLEM

Consider a requerce of frames i=0,1,2... At each frame, model the deservotion of the deject as a random continuous vector y_i , and model the object as having some interval state x_i (another random continuous vector) which we do not doserve and want to infer. $p(x_i|past)$

unobserved	Xo, XA, X2, X3,	Example: dynamics xi=xi-1+1	i: 1, 2, 3, 4, 5 Xi: 1, 2, 2.5, 3.5, 4.5 Y:: -2, -3.9, -5.1, -7, -8	also models unicitativity
doverved	yo, ya, yz, yz,	obscurations y:= -2xc	9: -2, -3.9, -5.1, -7, -8	1 2 2.5 3.5 4.5 X

Main problems:

- Prediction: given observations your yie, predict the next state xi: needs p(xi) your yie).
- Data association: which of the measurements at passe i tell is about the state xi? Also helds p(xi(yo,..., yin).
- Correction: after we do doserve the real, relevant measurements y; compute p(x; 1 yo, ... y;). * Independence assumptions (to simplify the model):
 - (1) Only the immediate part matters (Markour powers): p(xi|xo,...,xi-1) = p(xi|xc-1).
- 2) Meanveneuts depend only on the current state (se, y: is conditionally independent of all other measurements given xi): p(yo,...,y: (xo,...,xi) = p(yo(xo)... p(y: (xi).

Juferning the state at each frame is done inductively with Bayer the by ememiny that we know: . The initial state distribution p(xo)

The dynamic model p(x:1x:-1)] Part of the model definition (up to the user) but with parameter
The observation model p(y:1x:).] that may be turned for best performance.

Note: we propagate not the value of the state but its distribution (= entire set of possible states with their probabilities).

Recall: {

$$M \equiv manyinalisation : p(A) = \int p(A, B) dB$$

 $C \equiv conditioning : p(A, B) = p(A|B) p(B)$

- Initial step:
$$p(x_0|y_0) \xrightarrow{Bays} p(y_0|x_0) p(x_0) \xrightarrow{M} \frac{p(y_0|x_0) p(x_0)}{p(y_0)} \xrightarrow{M} \frac{p(y_0|x_0) p(x_0)}{\int p(y_0|x_0) p(x_0|dx_0)}$$

34)

- Atep i: assume we know $p(x_{i-1} | y_{0}, \dots, y_{i-n})$: Prediction: $p(x_i | y_{0}, \dots, y_{i-n}) \stackrel{M}{=} \int p(x_i, x_{i-1} | y_{0}, \dots, y_{i-n}) dx_{i-n} =$ $\stackrel{\leq}{=} \int p(x_i | x_{i-1}, y_{0}, \dots, y_{i-n}) p(x_{i-1} | y_{0}, \dots, y_{i-n}) dx_{i-n} \stackrel{M}{=} \int p(x_i, x_{i-1} | y_{0}, \dots, y_{i-n}) dx_{i-n} =$

$$= \int p(z_i | x_{i-1}, y_{0}, \dots, y_{i-1}) p(z_{i-1} | y_{0}, \dots, y_{i-1}) dx_{i-1} = \int p(z_i | z_{i-1}) p(z_{i-1} | y_{0}, \dots, y_{i-1}) dx_{i-1}.$$
equivalently,
we arguintly
$$= \underbrace{P(z_i, y_{0}, \dots, y_{i})}_{p(y_{0}, \dots, y_{i})} \underbrace{P(z_i, y_{0}, \dots, y_{i})}_{p(y_{0}, \dots, y_{i})} \underbrace{P(z_i, y_{0}, \dots, y_{i-1})}_{p(y_{0}, \dots, y_{i})} p(z_i | y_{0}, \dots, y_{i-1}). p(z_i | y_{0}, \dots, y_{i-1})}_{p(y_{0}, \dots, y_{i})} \underbrace{P(y_{0}, \dots, y_{i})}_{p(y_{0}, \dots, y_{i})} \underbrace{P(y_{0}, \dots, y_{i-1})}_{p(y_{0}, \dots, y_{i})} \underbrace{P(y_{0}, \dots, y_{i-1})}_{p(y_{0}, \dots, y_{i-1})}.$$

$$= p(y_i | x_i) p(x_i | y_{0}, \dots, y_{i-1}) \underbrace{P(y_{0}, \dots, y_{i-1})}_{p(y_{0}, \dots, y_{i})} \underbrace{P(y_{0}, \dots, y_{i-1})}_{p(y_{0}, \dots, y_{i-1})} \underbrace{P(y_{0}, \dots, y_{i-1})}_{p(y_{0}, \dots, y_{i-1})}.$$

17.2 LINEAR DYNAMICAL MODELS

If using linear transformations and gaussian deunities, the integrals can be solved analytically and yield Saussian deusities again (with certain means and covariance). Consider the \mathbb{R}^d , yi $\in \mathbb{R}^m$ for i = 0, 1, 2...:

<u>Opramis</u>: He state advances as a linear function of the previous state plug edditive Gaussian noise: Xi/Xi-1~ N(Di Xi-1, Zdi) or equivalently Xi = Di Xi-1 + Ndi where Di is a dxd matrix and Ndi ~ N(O, Zdi) is zero-mean noise with dxd covariance matrix Zdi. (Also passible to have a control input u: Zi = Di Xi-1 + Billi-1 + Ndi.)
<u>Observations</u>: the measurement is a linear function of the current state plus additive gaussian noise: yi/Xi ~ N(MiXi, Zmi) or equivalently yi= MiXi + Nmi where Mi is an Mxd matrix and Nmi ~ N(O, Zmi) is zero-mean noise with mxm covarience. matrix Emi.

- From a statistical learning point of view:
- Given known model parameters (Di', etc.), the <u>inference</u> problem is to infer the state sequence $\chi_0, \chi_1, \chi_2 \dots$ (or the refrience of posterior distributions for them) from the observotions requence $y_0, y_1, y_2 \dots$ (i.e., tracking).

- The learning problem (which we will not see) is to infer the model parameters from descript vegeties dote. We will amme the model parameters (Di, Edi, Mi, Emi for i= 0, 1, 2...) are known; they may be constant, or depend on the frame i.
- This seemingly simple model is very powerful. Examples for a moving object, calling $P_i = position (eg in 2D)$, $V_i = velocity \frac{dP_i}{dt}$, $a_i = acceleration \frac{dV_i}{dt}$.
- <u>Drifting points (random walk</u>): $x_i = p_i$, $D_i = I$ (commonly used for objects for which no better dynamic model is known). It implies we expect the state not to move too much - according to the noise covariance Ξd_i .
- Countaint velocites: $p_i = p_{i-A} + \Delta t$. Vi-A and $V_i = V_{i-A}$; state $x = \begin{pmatrix} P \\ V \end{pmatrix}$ with $D_i = \begin{pmatrix} I & A & I \\ O & I \end{pmatrix}$; commonly we down only the position: $M_i = (I O)$. [FIG. [A.1] there a physics point of view, knowledge of the hynamical equations would allow us to integrate the movement and deterministically predict p it any time in the furture without the need for discriminate model, do not include all possible factors that kuffume the myslem, and the external conditions may change, so we need indirect information about the state (the observations) to keep on track, and a way to deal with noise. Publicities models for tracking provide a framework to deal with uncertain data.
- MARKer Mass Constant acceleration: $p_i = p_{i-1} + \Delta t \cdot v_{i-1}$, $V_i = v_{i-1} + \Delta t \cdot a_{i-1}$, and $a_{i} = a_{i-1}$; Mate $x = \begin{pmatrix} P \\ Y \end{pmatrix}$ with $D_i = \begin{pmatrix} I & \Delta t \cdot I \\ 0 & I & \Delta t \cdot I \end{pmatrix}$; $M_i = (I \circ 0)$ (only desure position). F(G, I7.2]Effectively, by introducing v and a in the state we are introducing information about p_{i-1} , p_{i-2} . - <u>Periodic motion in 1D</u>: the position satisfies (say) $\frac{d^2p}{dt^2} = -p$ (harmonic oscillator) on equivalently $x = \begin{pmatrix} P \\ V \end{pmatrix}$, $\frac{dx}{dt} = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \times = S \times [prove it]$. If we integrate this 1^{st} -order ODE with a forward Euler method with step length Δt we obtain $x_i = x_{i-1} + \Delta t \cdot \frac{dx_{i-1}}{dt} = x_{i-1} + \Delta t \cdot x_{i-1}$

17.3 KALMAN FILTERING

Under the linear-gaunian assumption, the posterior distributions for prediction p(x: 1 yo,..., yi-1) and correction p(xi / yo,..., yi) turn out to be gaunien, thus all we need is to compute their means and covariances [proof: book]. The result is the kalman filter, which updates the mean and covariance of the prediction & correction distributions at each frame: Algorithm 17.2: Kalman filler FIG. 17.3-4 - Dynamicel model: Xi ~ S(DiXir, Ed:), Gi ~ S(MiXi, Zmi) Obernation - Hast assumption: user gives \overline{X}_{0}^{+} , Σ_{0}^{+} for $p(x_{0})$ - It each frame i, update: · Prediction p(xi) your yin) v d(xi, zi) with xi = Di xin, Zi = Edi + Di Zin Di. · correction placityon yil ~ N(xit, Zit) with xi = xi + Ki(yi - Mixi), $\Sigma_i^{\dagger} = (I - K_i M_i) \Sigma_i^{\dagger}, \text{ gain } K_i = \Sigma_i^{\dagger} M_i^{\dagger} (M_i \Sigma_i^{\dagger} M_i^{\dagger} + \Sigma_{m_i})^{-1}.$ always pd [prox it] Notes: (earier to understand in the 10 case where xi, yie (R) - Innovation or revidual: yi-Mizi = meanmement - prediction - It = It + Ki(Xi-Mili) = prediction + gain x residual = weighted everage of - { longe Emi = trust dynamics small Emi = trust dynamics € small E; - large Edi = trust measurent ⇐ large Z: Ly uncertain prediction (prediction more uncertain than dynamics) - Σ_i > Σ_{di} (correction less uncertain than prediction) $\Sigma_i^+ < \Sigma_i^-$ - If Edi, Emi are approx. contant then Ki, Ei, Ei quickly stabilize. - Ki and Zi can be computed before the observation yi arrives. * Forward backward mosthing: while p(x:1 yo,..., yi) is the best estimate of xing to frame i, an improved estimate of si for i < N is Astained from p(xi/yo,..., yN), le, taking into account the future behaviour of xi. For real-time tracking (eg. tracking a car in the apporte lane) we cannot want to get future measurements (we need to predict now), but for other applications we may afford collecting a few future measure ments before updatily, or we may be tracking offlike (eg. forunic tracking of a videstape).

Alporthun 17.3 : Kalman musching
$$F(\overline{b}, 17.5-6)$$

To get the distribution $P(Z_i | y_0, ..., y_N)$ at each frame i :
A. Forward kalman (ittle (nums forward in time): $P(Z_i | y_0, ..., y_i) \land cl(\overline{z_i}^{f+}, \Sigma_i^{f+})$
2. Bachward u u (u backward u u): $P(Z_i | y_{i+1}, ..., y_N) \land cl(\overline{z_i}^{f-}, \underline{z_i}^{f+})$
3. Combrine both to detain $P(Z_i | y_0, ..., y_N) \land cl(\overline{Z_i}^{*}, \underline{z_i}^{*})$ with $\begin{cases} \overline{z_i}^* = ((\overline{z_i}^{f+})^{-1} + (\overline{z_i}^{b-})^{-1})^{-1} \\ \overline{z_i}^* = Z_i^* ((\overline{z_i}^{f+})^{-1} \overline{z_i}^{f+} + (\overline{z_i}^{b-})^{-1})^{-1} \\ \overline{z_i}^* = weighted mean \mathcal{A} find (blowd casariances
 $\overline{z_i}^* = weighted mean \mathcal{A} find (blowd means)
- For backward musching, one problem is choosing the prior $P(Z_N)$: typical visitin applien$$

- For backwerd present is one product is one price price price (2N): "yprice how apprice time are argumetric in that we may have a good side of where the object started (p(Nox)) but not of where it ends (p(NN)). Ming p(XN (Yo, ..., YN)) **explored production datasets affer** (the forward fille prediction) is a dubious idea because it will clead to overconfident predictions (too narrow distributions).

* choosing the rearest reighbours: consider the predicted distribution of the measurements at frame i:

 $p(\mathcal{Y}_{i} = \mathcal{Y} \mid \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) \stackrel{\text{M.C}}{=} \int p(\mathcal{Y}_{i} = \mathcal{Y} \mid \mathcal{X}_{i}, \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) p(\mathcal{X}_{i} \mid \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) d\mathcal{X}_{i} \stackrel{\text{C}}{=} \\ = \int p(\mathcal{Y}_{i} \neq \mathcal{Y} \mid \mathcal{X}_{i}) p(\mathcal{X}_{i} \mid \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) d\mathcal{X}_{i} = \sum_{\text{states}i} (prob. given we are) \times (prob. we reached) \\ = \int p(\mathcal{Y}_{i} \neq \mathcal{Y} \mid \mathcal{X}_{i}) p(\mathcal{X}_{i} \mid \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) d\mathcal{X}_{i} = \sum_{\text{states}i} (prob. given we are) \times (prob. we reached) \\ = \int p(\mathcal{Y}_{i} \neq \mathcal{Y} \mid \mathcal{X}_{i}) p(\mathcal{X}_{i} \mid \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) d\mathcal{X}_{i} = \sum_{\text{states}i} (prob. given we are) \times (prob. we reached) \\ = \int p(\mathcal{Y}_{i} \neq \mathcal{Y} \mid \mathcal{X}_{i}) p(\mathcal{X}_{i} \mid \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) d\mathcal{X}_{i} = \sum_{\text{states}i} (prob. given we are) \times (prob. we reached) \\ = \int p(\mathcal{Y}_{i} \neq \mathcal{Y} \mid \mathcal{X}_{i}) p(\mathcal{X}_{i} \mid \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) d\mathcal{X}_{i} = \sum_{\text{states}i} (prob. given we are) \times (prob. we reached) \\ = \int p(\mathcal{Y}_{i} \neq \mathcal{Y} \mid \mathcal{X}_{i}) p(\mathcal{X}_{i} \mid \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) d\mathcal{X}_{i} = \sum_{\text{states}i} (prob. given we are) \times (prob. we reached) \\ = \int p(\mathcal{Y}_{i} \neq \mathcal{Y} \mid \mathcal{X}_{i}) p(\mathcal{X}_{i} \mid \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) d\mathcal{X}_{i} = \sum_{\text{states}i} (prob. given we are) \times (prob. we reached) \\ = \int p(\mathcal{Y}_{i} \neq \mathcal{Y} \mid \mathcal{X}_{i}) p(\mathcal{X}_{i} \mid \mathcal{Y}_{0}, \dots, \mathcal{Y}_{i-1}) d\mathcal{X}_{i} = \sum_{\text{states}i} (prob. given we are) \times (prob. we reached) \\ = \int p(\mathcal{Y}_{i} \neq \mathcal{Y} \mid \mathcal{X}_{i}) p(\mathcal{X}_{i} \mid \mathcal{Y}_{0}) d\mathcal{X}_{i} = \sum_{\text{states}i} (prob. given \mathcal{Y}_{i-1}) d\mathcal{X}_{i} = \sum_{\text{states}i} (prob. given \mathcal{Y}_{0}) d\mathcal{X}_{i} = \sum_{$

such on hocation & colour). We then choose the region with largest $p(y_i = y^n | y_{o_i} \dots y_{i-1})$. In other words, we choose the measurement closest to where we expect them. FIG. 17.8-9 This tends to nork because: - the background is usually significantly different from the object - the dynamic model helps. It fails if we bappen to have a big region which looks like the object and is near beetiess predicted by the dynamics; this also has the dauger that the Kalman filter believe it is doiry well so its coveriences are narrow, yet it that are consistent with the model predicteds.

- * goting and probabilistic data association: runtere of choosing the region most like the measurement:
 - 1. Gating: exclude all regions which we too different from the measurement, [eg. beyond 3 standard deviations from the predicted mean (adjust this for each practical problem).
 - 2. <u>Probabilistic data ensociation</u>: use all other measurements, weighing them according to their similarity to the prediction: $\sum p(y_i = y^n | y_{0, \dots, y_{i-i}}) \cdot y^n$.

HUMUS PART I: MIGH-LEVEL VISION: GEOMETRIC METHODS CH. 18: MODEL - BASED VISION

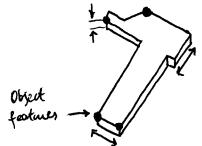

Object recognition as a correspondence problem: what is the diject pose (= position + orientation) that best matches the image ?

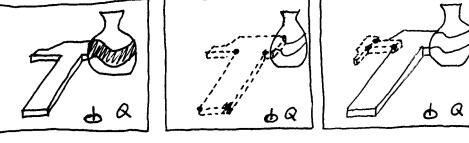

- Objects don't scatter features all over the image : the features of an object obey some constraints because of belonging to the object (which has a certain shape and dimensions) and because cameras produce fairly orderly projections.
- Then, knowing correspondences for a few features, we can obtain correspondences for many more features.

Assume we have a collection of geometric models of the objects of interest (the modelbase). I dea of the algorithm (hypothenise and test):

- Hypothenine a onexpondence between a allectron of image features and a collectron of deject features, and determine the camera matrix that projects the dejects onto the image. . We should generate few, good hypotheses and relatively quickly.
 - · Features: image points, eg. from intersections (implist feature: many correspondences so more rearch); local representation of image, eg. vector of filter outputs (complex feature : ferver correspondence, so less search).
- Generate a rendering of the diject (backprojection).
- compare the rendering with the image (venticition) and, it both are nefficiently similar, accept the hypothesis. - Needs reliable comparison methods (difficult issue).

Modelbase: object with Known Image with { cluster (given the 3 points) Bad correspondence (given the 3 points)

[39]

- Naively, many hypotheses: if M image features, Notject features in each diject and

L'affects then LNM possible correspondences (for each object, each image feature might correspond with any spicet feature).

- Geometric constraints limit the site of the search space, eg. the distances between projected points are constrained by the distances in the object and the 2D phytection (comera matrix). Thus we can determine the projection parameters from a few conspondences and then using the projection model we can determine the other correspondences (pose consistency or alignment methods).
- 18-2 OBTAINING MYPOTHESES BY POSE GNSISTENCY
- Frame group: group of features (image or deject features) that can be used to yield a camera hypothesis, eq:
 - · 3 points
 - · 3 directions and (to establish scale) a point

For all { doject frame groups D, image have groups F} For all conservations between elements of F and O Infer connector parameters Render the object with the connect matrix If the rendering confirms to the image, the object is present

For affine cameras, write the projection of world point P onto image point p with camera motive $M_{2,xy}$; $P = M\left(\frac{P}{2}\right)$. Thus, given a hypothetical conceptidence (P, P), we get 2 linear eqs. for the 8 unknowns in H:

$$P_{1} = m_{11}P_{1} + m_{12}P_{2} + m_{13}P_{3} + m_{14}$$
 So we need 4 points in general position to determine (1)

$$P_{2} = m_{21}P_{1} + m_{22}P_{2} + m_{23}P_{3} + m_{24}$$

$$\Rightarrow (re, a frame group of 4 points).$$

Once alg. 18.1 has tested for the presence of individual objects, we compare the corners matrices recognised for each pair of objects: if they are sufficiently different then the two hypotheses are incompatible. Note:

- Many true correspondences will venity ratisfactorily and yield approximately the same pose and camera matrix (eg. for different points of the same object).
- Some false conspondences (eg from clutter) will verify ratifactorily, but yield widely different estimates of pose and camera.

So we can durter the votes in pose space to letert the true pose - this is the Hough transform idea (so it inherits its problems re. selection of bucket rise, securitivity to noise).

18.5 VERIFICATION

- Illumination is a big problem: we don't know how the object should look for a given pose; this makes comparing pixel volues (between the image and the rendered object) unreliable. In some cases (eg. objects on a conveyor belt, with known illumination) this may not be a problem.
- Test: render the silhouette of the object (with the camera model) and compare it to edge points in the singer (edge proximity).
 - . Verification score: fraction of the length of predicted silhouette edges that he near, and have similar orientation, to actual image edges (should remove hidden lines from the silhouette).
 - # total name (edges in an image (eg. textured negotis), and we have no guarantee that we are using the good edges in the ventriention:
 + no edges where the model predicts edges ⇒ model is probably wrong.
 + edges n n n n n ⇒ model may a may not be wright F16:18.5]
 - In highly restured regions, most models it most poses can get high verification scores; a videly used approach is to tune the edge detector to smooth texture heavily but nithout blurning doject edges.
- Possible to use additional sources of information, eg. certain dijects are easily recognised by their distinctive texture.

PART VI: MIGH-LEVEL VISION: PROBABILISTIC AND INFERENTIAL METHODS CH. 22: FINDING TEMPLATES USING CLASSIFIERS

42

Many diject recognition problems involve locking for image windows that have a nimple shape and stylised content (= not many details or variations from Asject to diject): - Frontal faces at a coarse scale \underline{N} oval window + **I** for eyes, mouth + [] nose: **I** - Comma mounted on front of car sees top signs as having about the same shape happeniance. We search all mindows of a particular shape and site and test them for the object; if we don't know the site or orientation the diject may have, we also search over scale and orientation. (<u>template matching</u>). Some dijects can be found effectively by template matching (eg. faces, road signs) but others cannot (eg. people: too much variation in shapes). To build the test (that tells eg. whether an oval the sequence a face), we use <u>classifies</u> trained on a large out of examples.

22.1 CLASSIFIERS

- Assume we have a training set {(xn, yn)}, of labelled examples (supervised problem): feature vector xn and corresponding label yn (class of object that generated xn). - We want a rule (a function) that maps a given & to y (ie, that clampics a feature vector). It may be a probabilistic rule: ps(i |x). - Notation; "i > j" means (a point A) dans i is clampied as class j; "PS(i/x)" means our danifier strategy dansfier & as class i; "p(c(x)" means the true class-conditional probabilities (unknown). - We need to define the cost of mislabelling for each class, as this influence the choice of rule: call $L(i \rightarrow j)$ the loss function, which gives the relative cost when an deject of type i is chamilied as type j (with $L(i \rightarrow i) = 0$). Right function of a particular champion strategy S = expected loss under S: $R(5) = \sum_{i,j} P_5(i \rightarrow j) L(i \rightarrow j).$ Ez: x= patient $R(s) = 10 \cdot P_s(ill \rightarrow ill) + 2 \cdot P_s(ill \rightarrow ill).$ labely E { ill, ill } classifier : doctor

- Expected loss for a point x when choosing class
$$i: \sum_{i} p(j(x) \perp (j \rightarrow i))$$

 $\sum_{i} p(j(x) \perp (j \rightarrow i))$
 $p(x) \geq p(x) \perp (j \rightarrow i) = p(x) =$

- # EX: nearest-neighbours classifier (nonparametric): (k, l)-nearest-neighbours classifier; to classify X, find the k nearest neighbours of x is the training set and classify x with the class that has the highest number Q votes n if n > l, due refuse to classify. (k, o) = k-nearest-neighbours classifier, (1, o) = nearest-neighbour classifier. They work well despite their simplicity: if the number A examples is large, the risk is not far from the Bayes risk. Computationally, for a new x we weld to find the k nearest neighbours, which is costly in high dimensions : O(DN) (N example, $D \dim$) naively (checking the distance to every example) and not much faster with more sophisticated abgorithms. We also require a definition A distance.
- * Extimating and implaing performance:
 - . averfitting, crossiblidation
 - Bootghapping (dont onfuse with the botstrap): often a small number of training cares are the really important ones that determine the classifier behaviour, with the rest having only a small influence. To ensure we have those cases we need a large enough training net which means a higher computational cost. Mathematical A classifier small be detained at less cost of, rustead of training with the whole date, we first train with a subset of it, then edd the false positives and false megatives to the subset; we retrain again, etc.

22.2 BUILDING CLASSIFIERS FROM MISTOGRAMS

phypothenial

column totals

dans

Skin

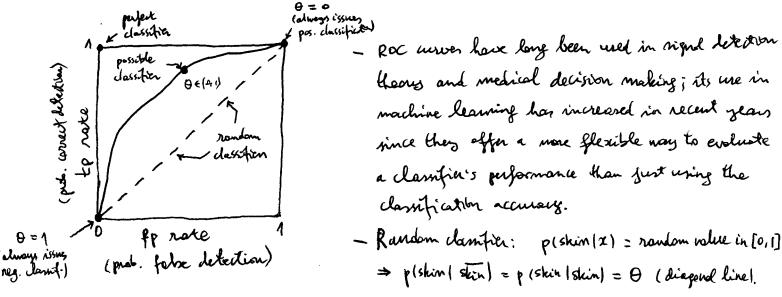

Skin

A histogram (normalised by the number of pixels to detain relative frequencies) can be used to estimate nonparametrically the class- conditional dewrity of the space dimension is low (so the number of bins required isn't too large).

★ Ex: finding skin pixels using a classifier: this is important for ef. getime-based interfaces.
Skin has a characteristic chain bistinion which allows to build a skin fixer by classifiering
pixels by their colour. Take x as R6B claur and model the class-conditional densities

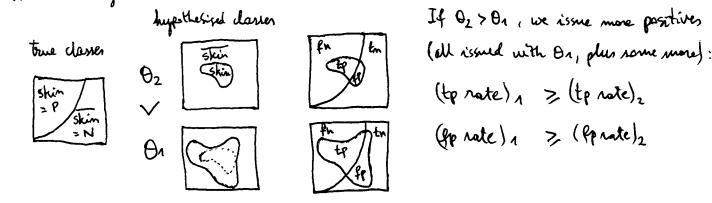

$$p(x|shin)$$
 and $p(x|shin)$ with bistograms; estimate $p(shin) = 1 - p(shin)$ as the proportion
of skin pixels on a (large) dataset. The Baye classifier then syields: $[F(G, 22-3]]$
 $p(Min(x).L(Main → shin) ≥ p(shin(x).L(shin → shin)) ⇔ $p(shin(x)) ≥ \Theta = \frac{L(shin → shin)}{L(shin → shin)} = lass$
Nowing the loss function L is equivalent to varying $\Theta \in [0, 1]$; this syields a family of
classifiers, one for each Θ . Each of these classifiers has a different place-positive and
false-negotive rate and can be conveniently represented by the receive operation of
tenistic (ROC) curve : $F(G, 22.4)$ (see Faweett: "An intro to Roc analysis", 2006).$

$$\begin{array}{c} (\text{influsion matrix (antilgency tilde]:} \\ (\text{influsion matrix (antilgency tilde]:} \\ \text{true class} \\ (\text{influsion matrix (antilgency tilde]:} \\ (\text{influx (antilgency tilde]:} \\ (\text{infl$$

Properties of Roc merves:

- Nondecreaning:

- Role Always above the diagonal (= random clanifiers) because, for a clanifican at (fp, tp) below the diagonal, negating its decision gives (1-fp, 1-fp) above the diagonal. EPF. Its Thue positives become false negatives and its false positives become true negatives]

- A discrete classifier (one which outputs a class label rather than a posterior probability) appears as a single point at its rate, (fp, tp).
- Conservative danifiers issue positives onte with strong enidence: near (0,0) Liberal ... "... with weak evidence: near (1,1).
- Invariant to choice of prior: changing p(skin) is equivalent to changing O. [lf: the rates of fp, tp do not depend on the notion of P to N.] Accuracy, precision de depend on the prior. Precision-recall airves are often used in information retrieval (retrieval = clamfication) instead of ROC usive.
- A different type of classifier (eg. a neural met) will yield a different ROC curve.
 One oriterion to compare ROC curve is by the area under the ROC curve (the large the better).
 Difficult to extend to >2 classes.
- * Ex: face finding assuming independent template responses (naive Bayes): in high dimensions, a histogram has too many trins; however, if (depending on the problem) we can afford to assume independence of the dimensions for the class-conditional probabilities, then $p(\chi_{1},...,\chi_{D}| \operatorname{class} i) = p(\chi_{1}| \operatorname{class} i) \cdots p(\chi_{D}| \operatorname{class} i)$ which can be built with D univariate histogram.
 - Assume the face occurs at a fixed, known scale (we could search smoothed and resumpled vervious of the image to find larger faces) and occupies a region of known shape (and a square for pointal faces, polygon for lateral faces). Buy we take a 64×67 square.

- Japlit this into n overlypping regions $r_1, ..., r_n$ (eg 4 (6x(6);
- Modelling the 64×64 image probabilitically for faces yields p(img) face = p(24,-424) face), which requires an n-drin histogram with k" bins (computationally infemble). Noive Bayes: model instead as p(img(face) = p1(22) face) --- 6n(22n) face), which requires n A-D histograms, or one 2D histogram for (level $\in \{1,...,k_{2}\}$, location $\in \{1,...,u_{3}\}$, with nk bins. some for p(ring) (face).

44

- The approximations (quantisation, naive Bayes) wild a poor generative model 4 face, but work well for recognizing faces. The quantistich also helps to remove minor variations caused by voice, this inequilarities, etc. [FIG. 22.5]

22.3 FEATURE SELECTION

- We want to find a set of features that best clamifies a dataset.
- Directly using ell the pixel volues with a classifier is not a good idea: the feature space to very complicated and we'd not have large margh dataacts to learn a good dampin.
- Mes, it is better to introduce a priori knowledge such as illumination or scaling, rather than praising (a huge number of) examples that represent difference in illumination or scaling.
- Assume we have an initial feature set (of the pixel internities) and that we wont to obtain a subset of features that are <u>linear combinations</u> of the initial one: while $x_1, \ldots, x_n \in \mathbb{R}^d$ (d features) the training set, we want a new training set with look defeatures $y_i = A x_i + br (Alxd, black)$.
- * <u>Inincipal component analysis (PCA)</u> selects features that maximize the variance of the data. Call $\mu \equiv \int_{n}^{\infty} \overset{\infty}{\Xi} \chi_{i}$ and $\Xi \equiv \int_{n}^{\infty} \overset{\infty}{\Xi} (\chi_{i} \mu)(\chi_{i} \mu)^{T}$ the mean and covariance of the training set (note: Z is a biased estimation while the sample covariance $\frac{h}{h-1}\Xi$ is unbiased). Define a new scalar zero-mean feature $\mathbf{M}(\chi) = \mathbf{M}_{n}^{T}(\chi - \mu)$ with $\mathcal{M} \in \mathbb{R}^{d}$. Then $\operatorname{Var}(\mathcal{K}) = \int_{n}^{\infty} \overset{\infty}{\Xi} \mathcal{M}(\chi_{i})^{2} \equiv \mathcal{M}^{T}\Xi \mathcal{K}$ which is maximized for fixed [[χ_{i}]], by the first eigenvector (associated with the hargest eigenvalue) of Ξ . If we require a 2^{nd} zero-mean scalar feature that maximize to \mathcal{V}_{1} then we obtain the 2^{nd} eigen-

Vector, it. We use define the result is quest from max to
$$(U^{T} \geq U)$$
 s.t. $U^{T} U = I$, $[\overline{H}]$
which is pitch by the leading l eigenvectors of Σ , $U = (u_{A_{1}}, ..., u_{R})$, be which to $(U^{T} \leq U)$:
= $\frac{1}{2}$ λ_{i} . (leading eigenvelops $\Lambda \equiv J$).
- Equivalently, the PCA features minimise the equival necoustimethan
ensure of the training set when projected to an L -dim. Linear subspace:
ensure zero-mean $X_{den} = (2A_{1}, ..., 2n) \Rightarrow \min_{U \geq U} ||X - UU^{T}X||_{F}^{2} = \lim_{t \geq U} |X - U^{T} \geq U$.
If. assume nomber(X) = $d < n$ so name $(UU^{T}X) \Rightarrow dL$, and write the SVD of X or X = ASB^T
with athogenal A_{ded} , B_{ned} , $S = diag(S_{11}, ..., Sd)$ containing the singular values $S_{1}, ..., 7Sd > 0$.
 $\Rightarrow \min_{u \geq U} ||X - \tilde{X}||$ is achieved by $\tilde{X} = UU^{T}X = A_{R} \leq B^{T}$ (the leading l singular value)
 $\Rightarrow U = A_{R}$ (note $\lambda_{i} = \frac{1}{n}S_{i}^{2}$ time $\Sigma = \frac{1}{n}XX^{T}$).
- PCA climinates traditioned the features (Hase which are $L = 0$ of the features); there appear
escinated with mult eigenvector does $u_{A_{1},...,U}$ be set X of I linear features.
- The PCA features are a uncorrelated [Iff. Their constraints, the dealing features that
(1) preserves the super values $a_{A_{1},...,U}$ and (2) minimizes the reconstruction error.
- Depending on the late net, PCA many or many as there give a good representation of
the dota. $\overline{F1(6, 22, 6, 7, 9)}$

* Identifying individuals with PCA.

- · Face identification: griven a face image, whose force is it? Two types of methods:
 - · Extract facial features (none, lips, eyes...) and match their geometry (height, with...) and relative position with descriptions stored in the latabase.
 - · Template matching: directly compare brightness patterns. Ex: eigenface.
- Eigenfairs are the principal components of a data set of face images:
 - Offline, given a database of face images: (1) subtract the mean and (2) project on the top l'eigenvectors (eigenface) of the covariance matrix. The resulting features for a given face are its coordinates in the eigenface being: $\overrightarrow{D} = a_1 \cdot \overrightarrow{\Box} + \cdots + a_l \cdot \overrightarrow{\Box}$.
 - . Online, given a new face image, we compute its features à (by notractily the mean and projecting on the eigenface) and apply a reasest-neighbour destrict.

- 1. If the reconstruction error > En, classify as non-face (too for from the face space).
- 2. Otherwise, let if be the face in the lataset that is closest to the test image in face space (eigenpaces). Then, if the distance to if is < E2 classify the test coording face as if, class classify it as unknown face (and optimally add if to the database and recompute the eigenface).

4 9

- EX: Turk & Pentland use 2500 128×128 images of 16 subjects, corresponding to all combinations of 3 face orientations, 3 head rale, and 3 highting conditions. [F16.22.8] [TAB.22.1]
- * Canonical variates (Fisher sisuiminant analysis):
- PCA does not use class information (is unsupervised) and thus need not yield features that are good for classification. [F(6. 22.9]
- Call µj, Zj the mean and covariance of class j; Sw = Ž Zj the sum of mithin-class covariances (assumed full-ranke); µ, SB the mean and covariance of all class means (between-class covariance). We want a set of axes that yield compact clusters for each class but separate clusters for different classes.
- specifically for a single scalar feature $x(x) = x_1^T x$, maximise the ratio of between class variance:
- Subsequent maximisation of the objective subject to orthogonality for the features yields the generalised eigenvectors associated with the leading I generalised eigenvalue.
- Uning l < d canonical variates reduces the dimension to I while best preserving the separation between classes.
- 22.4 (FEEDFORWARD) NEURAL NETS

- Feedforward neurol net = parametric function $f: x \in \mathbb{R}^{p} \rightarrow y \in \mathbb{R}^{q}$, biases eq with one fully-connected hidden layer : $f(x) = \Phi(W_{1} \cdot \Phi(W_{2}x + b_{2}) + b_{1})$ The nonlinearity $\Phi: \mathbb{R} \rightarrow \mathbb{R}$ is expliced elementwise; typical Φ : $\int - \frac{1}{2} \frac{1}{1+e^{-x}} \frac{1}{2} \frac{1}{1+e^$

- Flexible : with many hidden units, we can approximate a lot of functions.
- Trained to minimise the LSQ error on a training set {(xn, yn)} (supervised problem, nequession): min $E(W,b) = \frac{1}{2} \sum_{n=1}^{\infty} ||y_n - f(x_n; W, b)||^2$. Any LSQ aptimisation algorithm is valid (eg. Gauss-W,b Nonton, Levenberg-Marquardt) but often one just uses gradient descent because W has many weight.
- The gradient $\frac{\partial E}{\partial W}$ can be computed larger by larger using the chain rule (<u>backpropagation</u>; see back). However, computing the exact gradient needs to run over all examples xn ("batch learning), which is computationally costly. Instead, we can compute the gradient for one example alone and update the parameters immediately ("online" learning, stochastic gradient descent), cycling over all examples (possibly in random order). For sufficiently small product steps both the batch and (on the everage) the online versions decrease the error.
- Model relation for the number of units and layers: in practice, related by trial and error.
- To produce a classifier with a neural net, we need to approximate the function p(i|z), but we don't know the value of $y_n = p(\cdot|x_n)$. However, we can use $y_n = (0 \dots 1 \dots 0)$ (a 1 for the class of x_n) and then classify x_n into the largest component of f(x).
- * Finding faces using neural nets: the neural net acts is a clampic which is applied to windows of the simage, possibly at different scales (template matching).
 - Correction wit illumination:
 - A simple illumination model is a linear ramp = one rise is dark, the other bright,
 with a smooth transition (eg. face illuminated from the right) ⇒ fit a linear ramp to the intervity value, and subtract it from the image nindow.
 - · Can also do this to the log-intensity (the illumination is approximately additive in the log domain), but not much difference in practice.
 - · Histogram-equalise the vindow to ensure its histogram is the same as that of a set of reference image. [F16.22.14]
 - Correction with face orientation (RBK, 1998): (1) estimate the orientation of the window with one neural net, (2) rotate mindow to vertical, (3) classify this with a second neural net. [F16. 22.15-16]
- * Concoluctional neural net: feedfind neural net but not fully connected; each layer acts as a set of matically localised filters, so that the sequence of layers acts as a sophisticalled feature extractor, with the last layer being a classifica. Ex: for handwritten characters, oriented bar filters are useful: given a map of orientation bars in the image (layer 1), layer 2 extracts spatial relations between bars, ck. We specify by mand the exclutecture (# layers, connectivity, between them, # limits) and train all praameters together. The net rectifies the handwritten character, achieving inversion to scaling, notation; translation. F16. 22. 17-18 + description.

$$\begin{split} & \underbrace{\text{EM}}_{n} = \text{M}_{n} \text{p}(\mathbf{x}_{1}, \mathbf{m}) = \text{H}_{n} \text{p}(\mathbf{x}_{1}, \mathbf{m}), \quad p(\mathbf{x}) = \underbrace{\sum}_{m \in \mathbb{N}} \text{H}_{m} \text{p}(\mathbf{x}_{1}, \mathbf{m}), \quad p\text{answelles} \quad \Theta = \{\text{H}_{m}, |\underline{\mu}_{m}| \leq m\}_{n=1}^{m}, \\ & \text{dy}_{n} \text{likelihand} \quad L(\theta) = \underbrace{\sum}_{n} \log p(\mathbf{x}_{n}) - \lambda \underbrace{\sum}_{n} \text{H}_{m} = \underbrace{\sum}_{n} \log \underbrace{\sum}_{n} \text{H}_{n} p(\mathbf{x}_{n}, \mathbf{m}) - \lambda \underbrace{\sum}_{n} \text{H}_{n} \\ & \text{given surple} \{\mathbf{x}_{n}\} \\ & \text{effectives probabilities} \quad \{y_{n}, y_{n}\} = \underbrace{\sum}_{n} \log p(\mathbf{x}_{n}) - \lambda \underbrace{\sum}_{n} \text{H}_{m} \\ & \text{effectives probabilities} \quad \{y_{n}, y_{n}\} = \underbrace{p^{dd}(\mathbf{x}_{n}, \mathbf{m}) \text{ as if } \mathbf{m}_{n} \text{ use becam.} \\ & \text{for every probabilities} \quad \{y_{n}, y_{n}\} = \underbrace{p^{dd}(\mathbf{x}_{n}, \mathbf{m}) \text{ for } \mathbf{H}_{n}}_{\substack{n \in \mathbb{N}}} = \frac{p^{dd}(\mathbf{x}_{n}, \mathbf{m}) \text{ for } \frac{p^{dd}(\mathbf{x}_{n}) \text{ for } \mathbf{h}_{n}}{\sum} p^{dd}(\mathbf{x}_{n}, \mathbf{h}) \text{ for } \frac{p^{dd}(\mathbf{x}_{n}) \text{ for } \mathbf{h}_{n}}{\sum} p^{dd}(\mathbf{x}_{n}, \mathbf{h}) \text{ for } \frac{p^{dd}(\mathbf{x}_{n}, \mathbf{h})}{\sum} = \underbrace{p^{dd}(\mathbf{x}_{n}, \mathbf{h}) \text{ for } \frac{p^{dd}(\mathbf{x}_{n}) \text{ for } \mathbf{h}_{n}}{\sum} p^{dd}(\mathbf{x}_{n}, \mathbf{h}) \text{ for } \frac{p^{dd}(\mathbf{x}_{n})}{\sum} p^{dd}(\mathbf{x}_{n}, \mathbf{h}) \text{ for } \frac{p^{dd}(\mathbf{x}_{n}, \mathbf{h})}{\sum} p^{dd}(\mathbf{x}_{n}, \mathbf{h}) \text{ for } \frac{p^{dd}(\mathbf{x}_{n}, \mathbf{h})}{\sum} = \underbrace{p^{dd}(\mathbf{x}_{n}, \mathbf{h}) \text{ for } \frac{p^{dd}(\mathbf{x}_{n}, \mathbf{h})}{\sum} p^{dd}(\mathbf{x}_{n}, \mathbf{h})} = \frac{p^{dd}(\mathbf{x}_{n}, \mathbf{h})}{\sum} \frac{p^{$$

Thus the increase in log-likelihood is at least as much as the increase in Q, but Q is easier to aptimise (no $\log \sum_{m}$). Lawer bound: $L(Q) \ge Q(Q|Q^{old}) + K$ with $K = L(Q^{old}) - Q(Q^{old}|Q^{old})$.
